FOREWORD

This is the final report of the research conducted under Phase II of the Iowa State Highway Commission Research Project No. HR-136. The project was initiated in February 1968.

This project was coordinated with the Iowa State Highway Commission Research Project No. HR-137, Time-Dependent Deformation of Non-Composite and Composite Sand-Lightweight Prestressed Concrete Structures (see report No. 69-1, dated February, 1969). Both projects were directed by Drs. D.E. Branson and B.L. Meyers.

Acknowledge is made of the assistance of Messrs. S.E. Roberts, Research Engineer, C. Pestotnik, Bridge Engineer, and Y.H. Gee, Assistant Bridge Engineer of the Iowa State Highway Commission; Mr. J.H. Boehmler, Jr., President, Prestressed Concrete of Iowa, Inc.; and G. Anderson and P. Kline, Graduate Students, University of Iowa.

The authors would also like to acknowledge Idealite Co., Denver, Colorado; Hydraulic Press Brick Co., Brooklyn, Indiana; Carter-Waters Corp., Kansas City, Missouri; and Buildex, Inc., Ottawa, Kansas for donating materials used in the experimental program.

The opinions, findings and conclusions expressed in this publication are those of the author and not necessarily those of the Iowa State Highway Commission.

ABSTRACT

This report is concerned with the prediction of the long-time creep and shrinkage behavior of concrete. It is divided into three main areas.

1. The development of general prediction methods that can be used by a design engineer when specific experimental data are not available.

2. The development of prediction methods based on experimental data. These methods take advantage of equations developed in item 1, and can be used to accurately predict creep and shrinkage after only 28 days of data collection.

3. Experimental verification of items 1 and 2, and the development of specific prediction equations for four sand-lightweight aggregate concretes tested in the experimental program.

The general prediction equations and methods are developed in Chapter II. Standard Equations to estimate the creep of normal weight concrete (Eq. 9), sand-lightweight concrete (Eq. 12), and lightweight concrete (Eq. 15) are recommended. These equations are developed for standard conditions (see Sec. 2.1) and correction factors required to convert creep coefficients obtained from equations 9, 12, and 15 to

valid predictions for other conditions are given in Equations 17 through 23. The correction factors are shown graphically in Figs. 6 through 13.

Similar equations and methods are developed for the prediction of the shrinkage of moist cured normal weight concrete (Eq. 30), moist cured sand-lightweight concrete (Eq. 33), and moist cured lightweight concrete (Eq. 36). For steam cured concrete the equations are Eq. 42 for normal weight concrete, and Eq. 45 for lightweight concrete. Correction factors are given in Equations 47 through 52 and Figs., 18 through 24.

Chapter III summarizes and illustrates, by examples, the prediction methods developed in Chapter II.

Chapters IV and V describe an experimental program in which specific prediction equations are developed for concretes made with Haydite manufactured by Hydraulic Press Brick Co. (Eqs. 53 and 54), Haydite manufactured by Buildex Inc. (Eqs. 55 and 56), Haydite manufactured by The Cater-Waters Corp. (Eqs. 57 and 58), and Idealite manufactured by Idealite Co. (Eqs. 59 and 60). General prediction equations are also developed from the data obtained in the experimental program (Eqs. 61 and 62) and are compared to similar equations developed in Chapter II.

Creep and Shrinkage prediction methods based on 28 day experimental data are developed in Chapter VI. The methods are verified by comparing predicted and measured values of the long-time creep and

shrinkage of specimens tested at the University of Iowa (see Chapters IV and V) and elsewhere. The accuracy obtained is shown to be superior to other similar methods available to the design engineer.

NOTATION

A	= air content in percent
B	= bags of cement per cubic yard
C_t	= creep coefficient at time t, defined as ratio of creep strain to initial strain
C_u	= ultimate creep coefficient
C. F.	= correction factor to account for conditions other than standard
c, d	= empirical constants in standard creep equation
e, f	= empirical constants in standard shrinkage equation
F	= ratio of fine aggregate to total aggregate (by weight), expressed as a percentage
H	= ambient relative humidity in percent
i	= subscript denoting initial value
LA	= subscript denoting loading age
S	= slump of concrete in inches
sh	= subscript denoting shrinkage
T	= minimum thickness of member in inches
t	= time in days
u	= subscript denoting ultimate value
ϵ_i	= initial strain due to applied load

NOTATION (cont.)

$(\epsilon_{sh})_t$ = shrinkage strain at time t

$(\epsilon_{sh})_u$ = ultimate shrinkage strain

σ_i = initial applied stress

Chapter 1

INTRODUCTION

1.1 Background Information

It has been suggested that the three main criteria for the serviceability of structures are:

1. the limit state of excess deflection
2. local damage; and
3. collapse. ⁽¹⁾

Work being carried out at the University of Iowa, under the sponsorship of the Iowa State Highway Commission, has been concerned with the limit state of deflection. In particular, the projects "Creep and Shrinkage Properties of Lightweight Concrete Used in the State of Iowa" (HR-136), and "Time-Dependent Deformation of Non-Composite and Composite Sand-Lightweight Prestressed Concrete Structures" (HR-137) were designed to investigate the long term state of limit deflection.

The familiar creep prediction methods developed by Ross ⁽²⁾ and Jones et al. ⁽³⁾ were combined and fairly accurate methods to estimate the creep of shrinkage of concrete mixes made with Idealite aggregate were suggested in the Phase 1 report of Project HR-136 ⁽⁴⁾. A close evaluation of these methods indicate the following:

1. Using the methods described in Reference (4), creep and shrinkage characteristics can be adequately predicted from equations derived based on 100-day creep and shrinkage data.
2. For structures made with the aggregate investigated, predictions can be made using the equation suggested in Reference (4) without gathering additional data.
3. The general form of the creep equation used in Reference (4) although yielding adequate results, does not seem to accurately represent measured creep values from 1 day to 28 days.
4. The general form of the shrinkage equation suggested in Reference (4) seems to adequately represent measured shrinkage values for all time intervals.

Building on the procedures developed in Reference (4), Branson, Meyers, and Kripanarayanan⁽⁵⁾ modified the suggested creep and shrinkage prediction methods and proposed the following standard prediction equations.

$$C_t = \frac{t^c}{d + t^c} C_u \quad (1)$$

$$\epsilon_{sh} = \frac{t^e}{f + t^e} (\epsilon_{sh})_u \quad (2)$$

where

C_t = creep coefficient at any time t ; ϵ_{sh} = shrinkage strain at any time t ; $c, d, e,$ and f are empirical constants; C_u = ultimate creep

coefficient and $(\epsilon_{sh})_u$ = ultimate shrinkage strain. It was further suggested in Reference (5) that $c = 0.6$, $d = 11.0$ and $C_u = 1.75$; $e = 1.0$, $f = 23.6$, $(\epsilon_{sh})_u = 590 \times 10^{-6}$ in/in, for the moist cured concrete used in that study.

It is apparent from comparisons with measured data that the form of the creep prediction equation suggested in Equation (1) is more representative of the full range of creep behavior than the form originally suggested by Ross⁽²⁾ and used in Reference (4). Such a comparison is made in Fig. 1.

1.2 Review of Literature

Much has been written on the creep of concrete in the last 70 years⁽⁶⁾ and a number of authors^(7, 8, 9, 10) have adequately reviewed the subject. Since this report is primarily concerned with prediction methods and their accuracy this section will be limited to a review of these methods.

Prediction methods that might be useful to the engineer fall into two general categories. The first category, expressing the creep time relation in the form of an equation, usually requires that one or more empirical constants be determined experimentally. The second category, expressing creep using a standard curve which can be modified by a number of factors to allow for various mix and storage conditions, does not require experimental data but is usually less

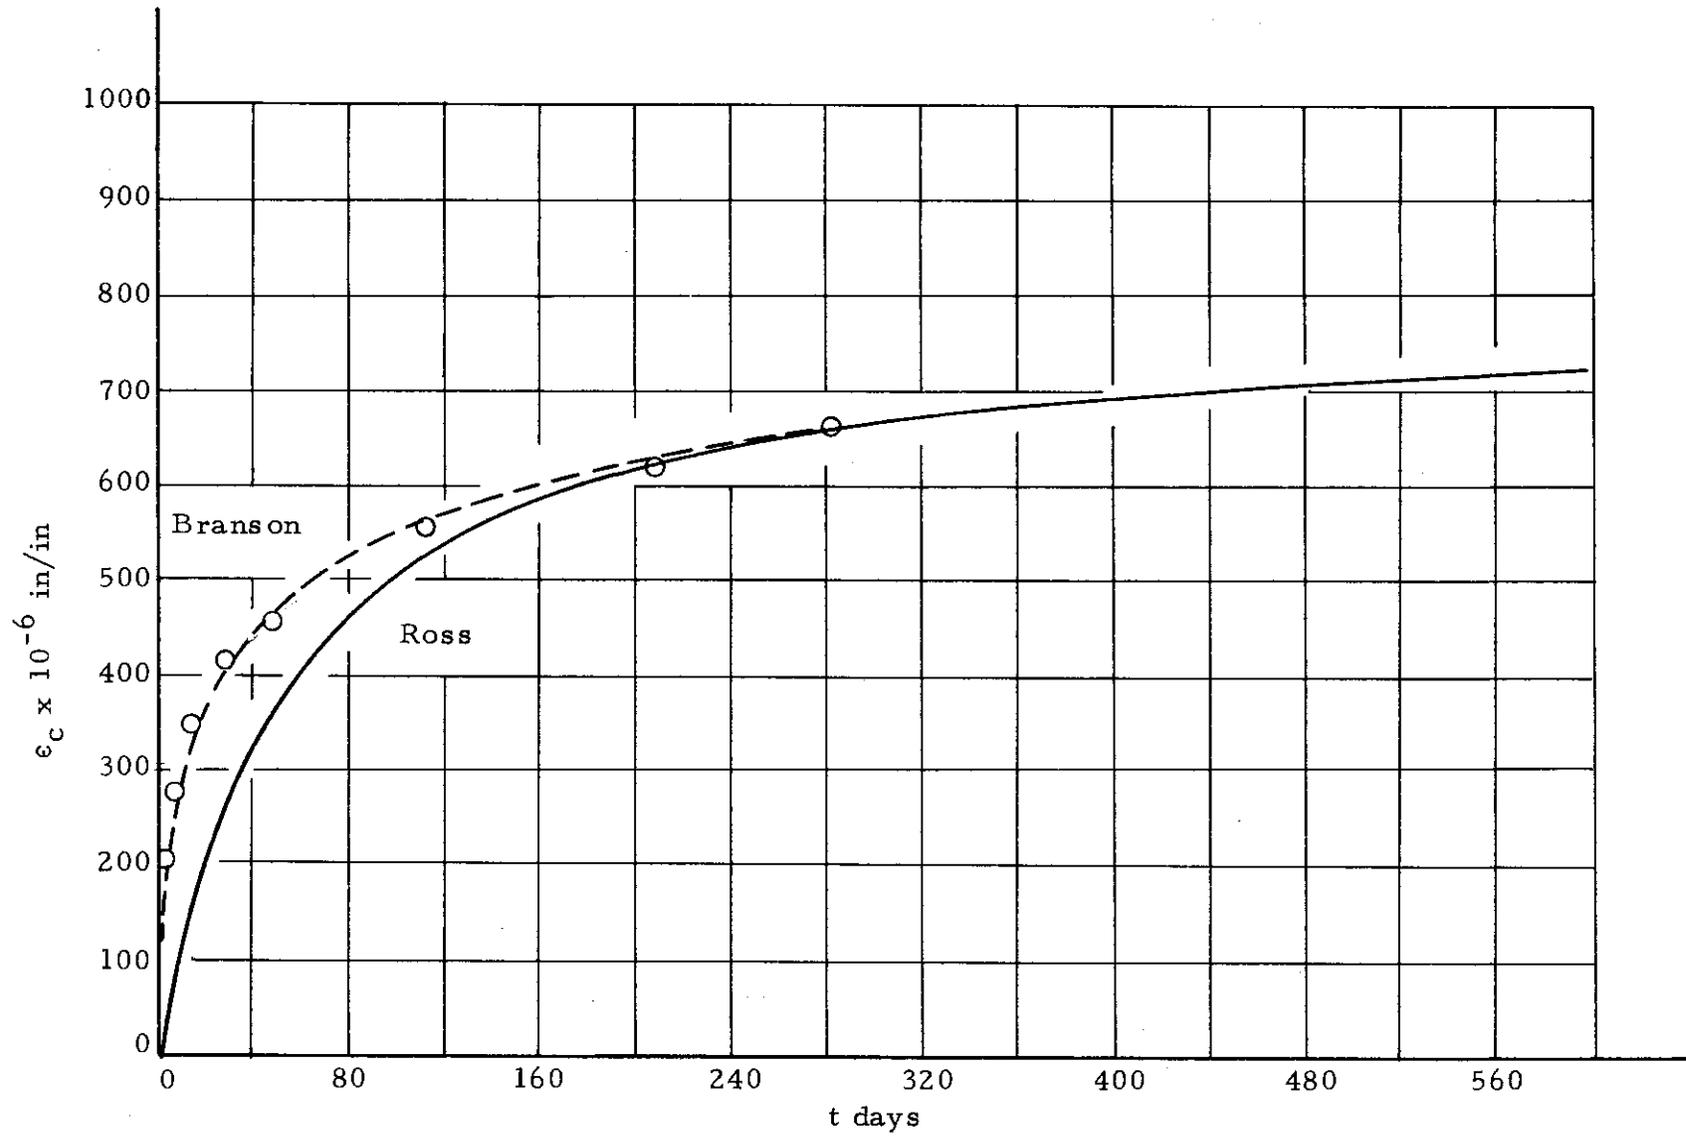

Fig. 1 Predicted Creep Using Ross Equation vs. Branson Equation

accurate than the use of an empirical equation based on actual measurements.

About a dozen exponential or hyperbolic equations have been suggested in the literature. The exponential equations, which have the disadvantage of not approaching a finite limit, are of doubtful practical value because they are usually unwieldy or require extended periods of data collection. Such equations have been proposed by Thomas⁽¹¹⁾, McHenry⁽¹²⁾, Saliger⁽¹³⁾, Shank⁽¹⁴⁾, and Troxel et al.⁽¹⁵⁾.

A number of hyperbolic equations, which do approach a finite limit, have also been suggested. Those used most often are the equations of Ross⁽²⁾

$$c = \frac{t}{a + bt} \quad (3a)$$

and Lorman⁽¹⁶⁾

$$c = \frac{mt}{n + t} \sigma \quad (3b)$$

where c = creep, t = time, σ = stress, and a , b , m , and n are empirical constants.

The methods using standard creep curves can be represented by those suggested by Jones, Hirsch, and Stephenson⁽³⁾, and Wagner⁽¹⁸⁾. Jones et al.⁽³⁾ use a standard curve which is valid for specific mix and storage parameters. The standard curve is corrected for other conditions using a set of correction factors. Wagner's method differs only in that standard values of ultimate specific

creep are given in lieu of the standard creep curve.

An excellent check for any of the methods described above was supplied by Troxell, Rapheal and Davis⁽¹⁵⁾. Based on an extensive 30-year study they concluded that approximately 1/4 of the 20-year creep occurred during the first two weeks under load, about 1/2 in the first 2 or 3 months, and about 3/4 in the first year. An additional 10% occurred the second year and the remaining 15% required 18 years.

The accuracy of any method can be evaluated in terms of an error coefficient M suggested by Neville and Meyers⁽⁷⁾.

$$M = \sqrt{(C_t - C_1)^2 / n} / C_1$$

where C_t = creep after one year predicted from measured creep after t weeks under load; C_1 = actual creep after one year under load; n = number of specimens or experimental sets for which creep was observed at time t. M is thus analogous to the coefficient of variation but deviation is measured from the true creep.

In their paper Neville and Meyers⁽⁷⁾ suggested that the error coefficient for most available methods is as shown in Fig. 2. The data shown in the figure represents only prediction based on a fixed amount of experimental data. It can be concluded that in order to predict creep within an error coefficient of 10%, twenty weeks of data is required. A typical prediction using the methods of Jones et al.⁽³⁾, and Wagner⁽¹⁸⁾ is shown in Fig. 3.

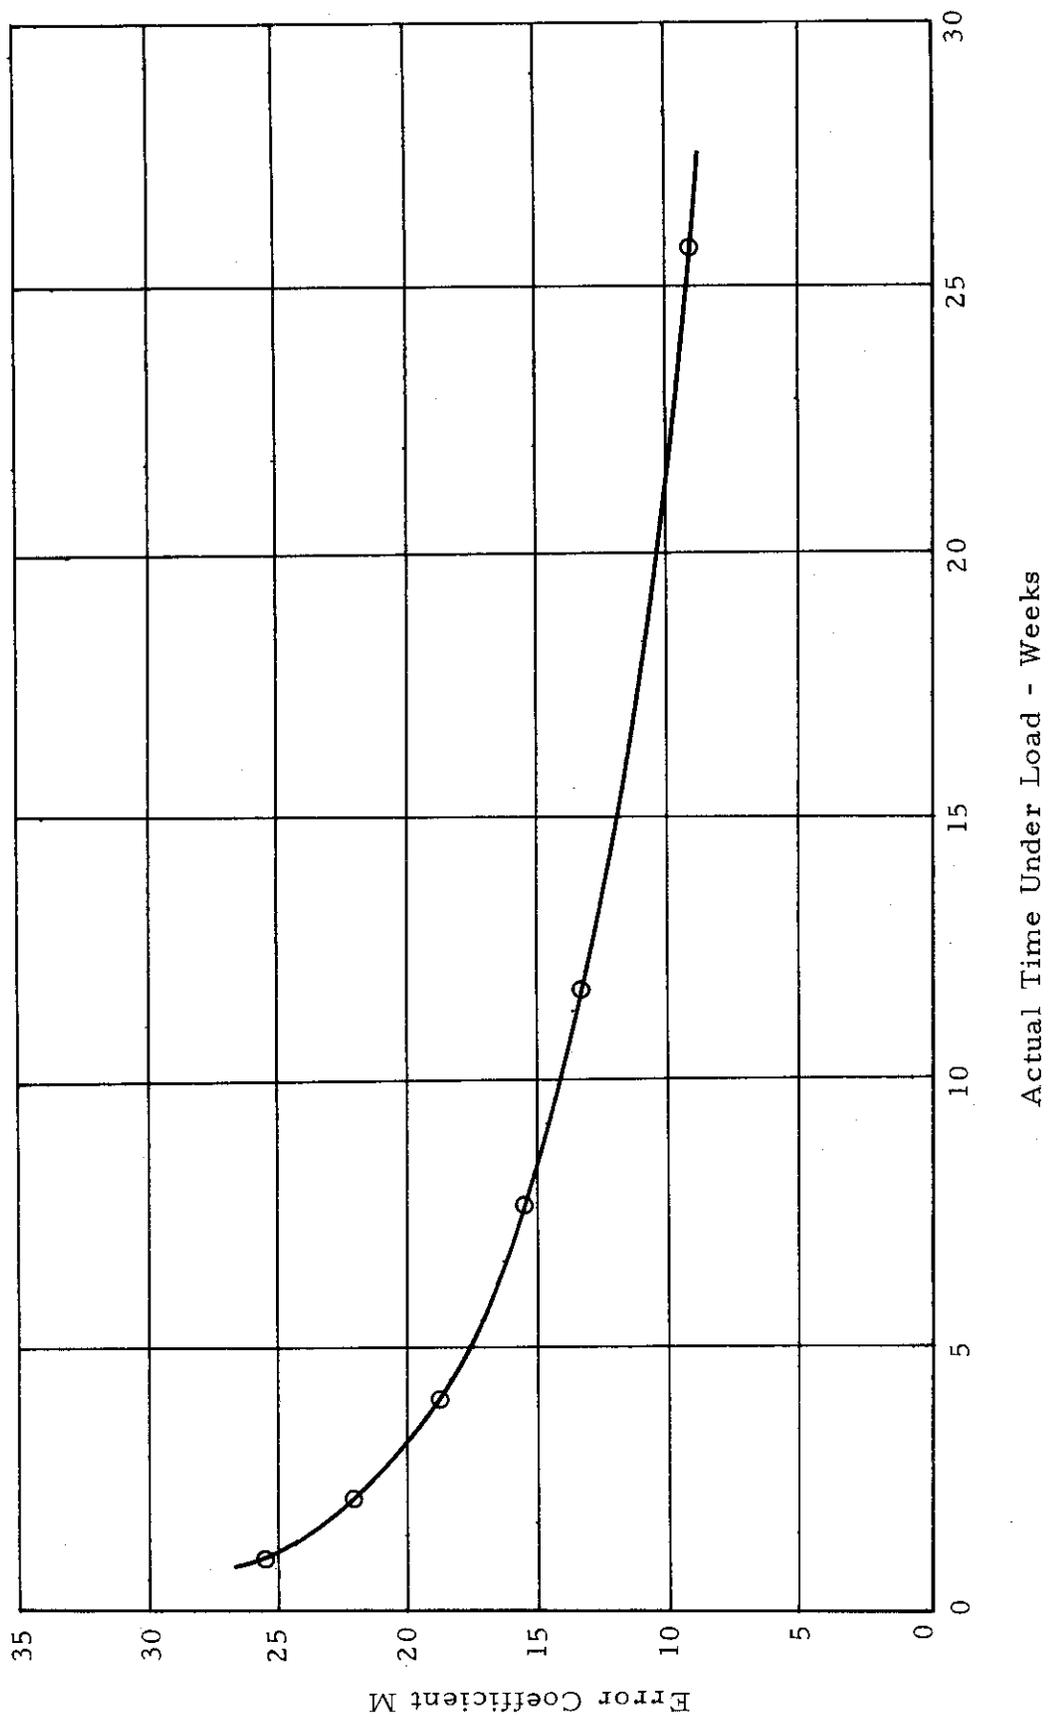

Fig. 2 Accuracy of Predicting 1 Yr Creep From Short Time Tests

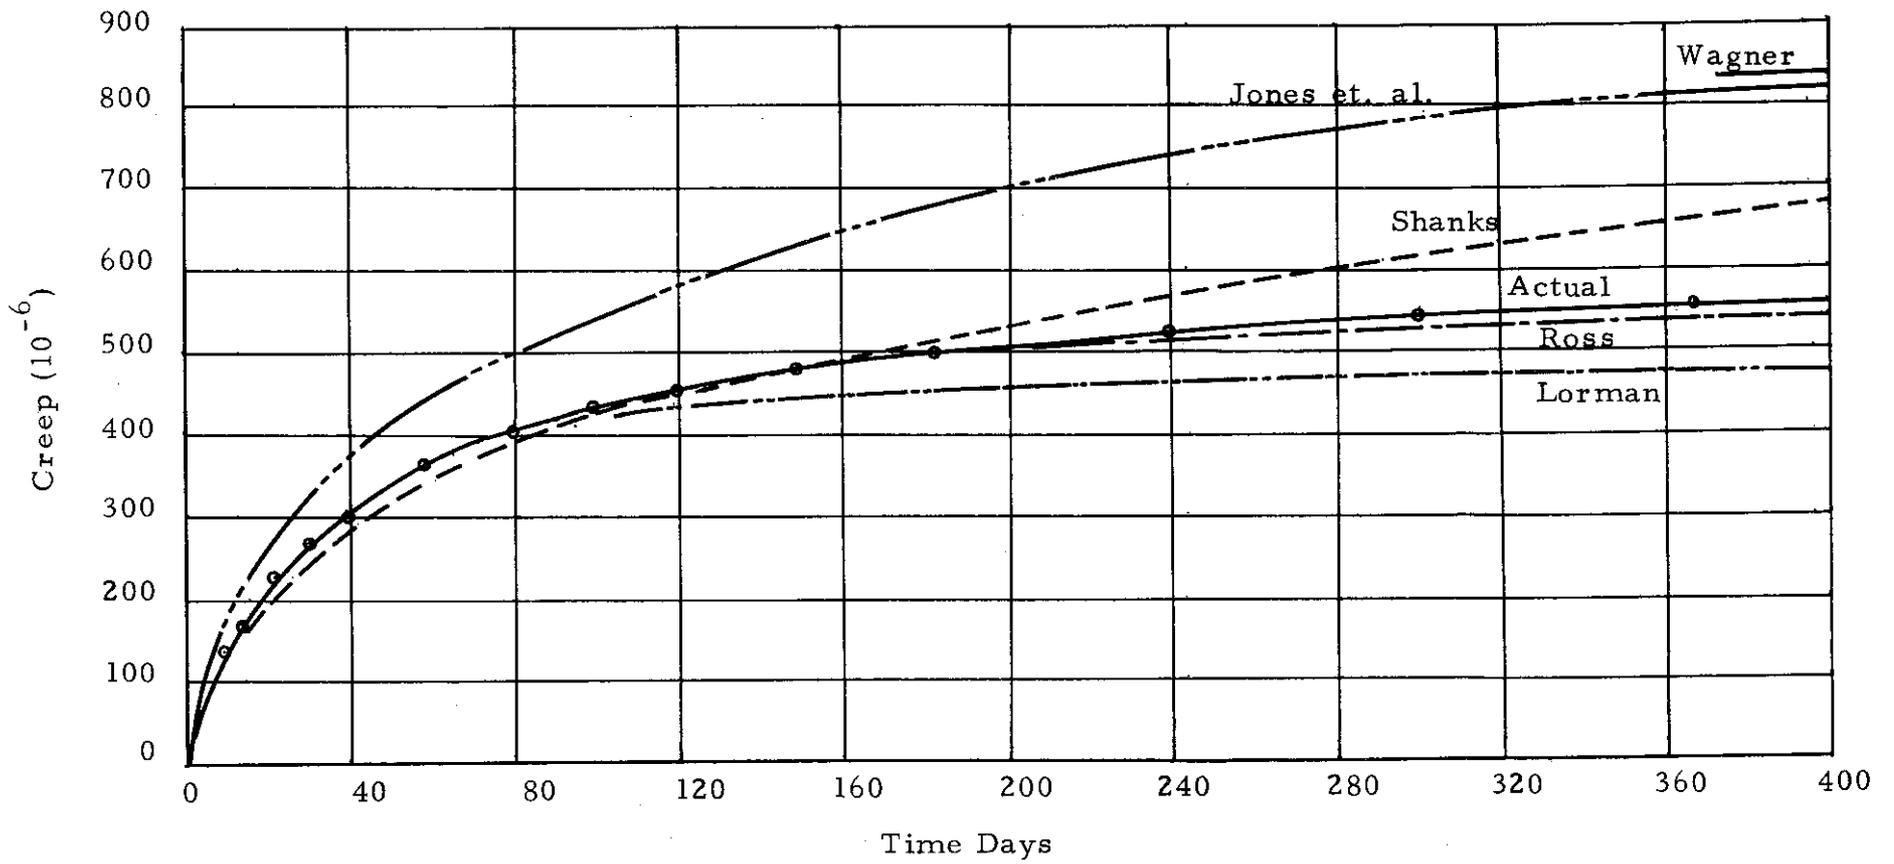

Fig. 3--Comparison of Prediction Methods

1.3 Statement of the Problem

Based on the above brief review of available prediction methods and the work carried out at the University of Iowa^(4 and 5) it is suggested that the following developments are necessary so that the designer can control the deflection of structures within acceptable and specified limits of uncertainty.

1. Develop accurate general prediction methods that do not require data collection.

2. Develop prediction methods that require a minimum of data collection (less than 20 weeks). In many cases the inherent uncertainties of prediction without data will not result in deformation estimates not sufficiently accurate for many structures (e.g., nuclear reactors, etc.).

The research reported herein is concerned with these areas as well as the development of accurate relations that can be used to predict the creep and shrinkage behavior of lightweight aggregate concretes available in the State of Iowa.

Therefore the work described in this report can be divided into three main sections.

1. The development of general prediction methods for creep and shrinkage of concrete based on the mathematical representation for time-dependent deformation suggested by Branson et al.^(5, 17).

2. An experimental verification of the methods developed in Item 1 above. The experimental program was carried out using a

number of lightweight aggregate concretes available in the State of Iowa. Accurate relationships that can be used to predict creep and shrinkage behavior of these materials are recommended.

3. The development of creep and shrinkage prediction methods based on only 28 days of data collection. These methods take advantage of the increased accuracy of the equations suggested by Branson et al. (5).

Chapter 2

GENERAL PREDICTION METHODS: CREEP AND SHRINKAGE

2.1 Creep of Concrete

It has been demonstrated that creep of a concrete specimen with fixed mix parameters and storage conditions can be predicted using an equation in the form of Eq. (1) ⁽⁵⁾. Creep of a specimen subjected to other than standard conditions can then be estimated by applying experimentally determined general correction factors to the value obtained using the standard equation. This type of design procedure is similar to those proposed by Branson et al. ⁽⁵⁾, Jones et al. ⁽³⁾, and the CEB report ⁽¹⁹⁾. This technique has been adopted in this report, and all standard equations are developed for the following standard conditions: 3" or less slump, 40% ambient relative humidity, and loading ages of 7 days for moist cured and 2-3 days for steam cured concretes.

In order to determine a general relationship, creep data from References 3, 4, 20-29 (tabulated in the Appendix) were reduced to the above-mentioned standard conditions using correction factors described in Sections 2.2 and 2.4 of this report. A creep coefficient versus time curve was prepared for each specimen from which ultimate creep coefficients were extrapolated. The data were then normalized in terms of the ultimate creep coefficient and are plotted in Fig. 4.

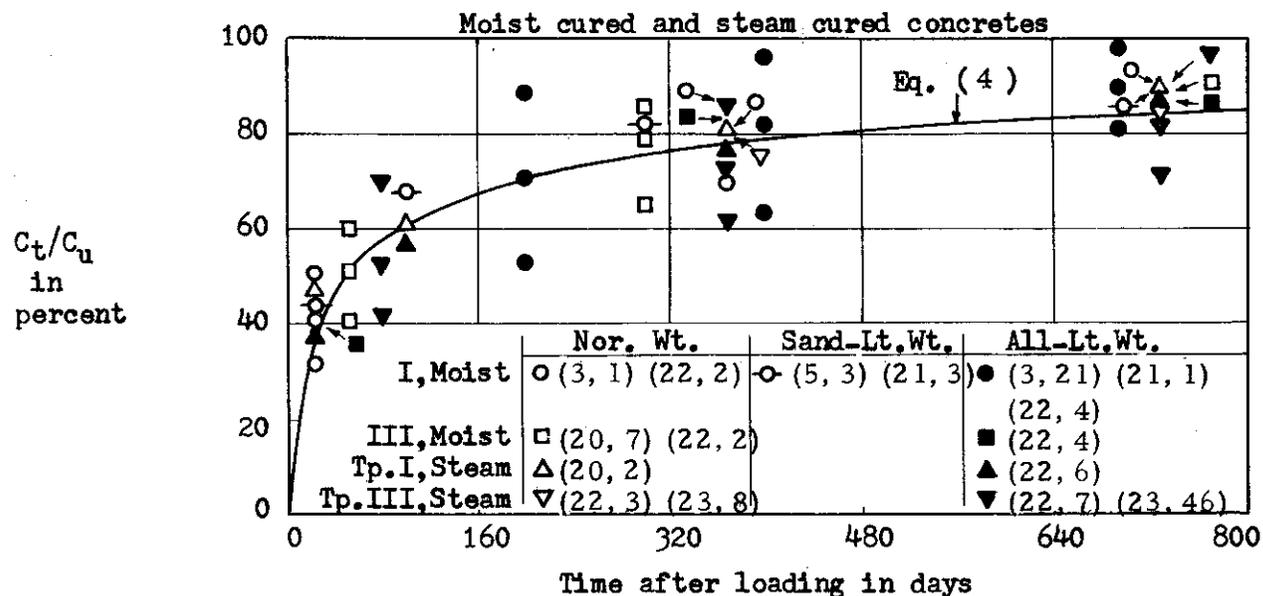

Fig. 4--Creep coefficient in percent of ultimate creep coefficient versus time curve using Eq. (4) for moist cured and steam cured concretes, and comparison with data. Loading ages are 7 days for moist cured and 2-3 days for steam cured concretes. In each set of parentheses, the first and second numbers, respectively, refer to the source of the data and the number of specimens from that source. Three data points shown for a specific time refer to the upper and lower limits and the average value for the data. Where only one data point is shown, the range of the data is too small to indicate

In most cases, three data points are shown for a particular specimen category and time. They represent the upper and lower limit and average values for these data. Only one data point is shown for a specific value of time when the spread between upper and lower values is small. Eq. (4) was derived by fitting a curve to the average values of the data plotted in Fig. 4.

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} C_u \quad (4)$$

The same data are shown in Fig. 5 where creep coefficients are plotted versus time after loading in days. From this plot specific equations can be determined for upper bound, average, and lower bound values. These equations are

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} 4.15 \quad (5)$$

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} 2.35 \quad (6)$$

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} 1.30 \quad (7)$$

These data can also be further separated and a similar set of equations developed for normal weight concrete only, sand-lightweight concrete only and all lightweight concrete only.

For the normal weight concrete data, the upper-limit, average-value, and lower-limit curves, respectively, are given by:

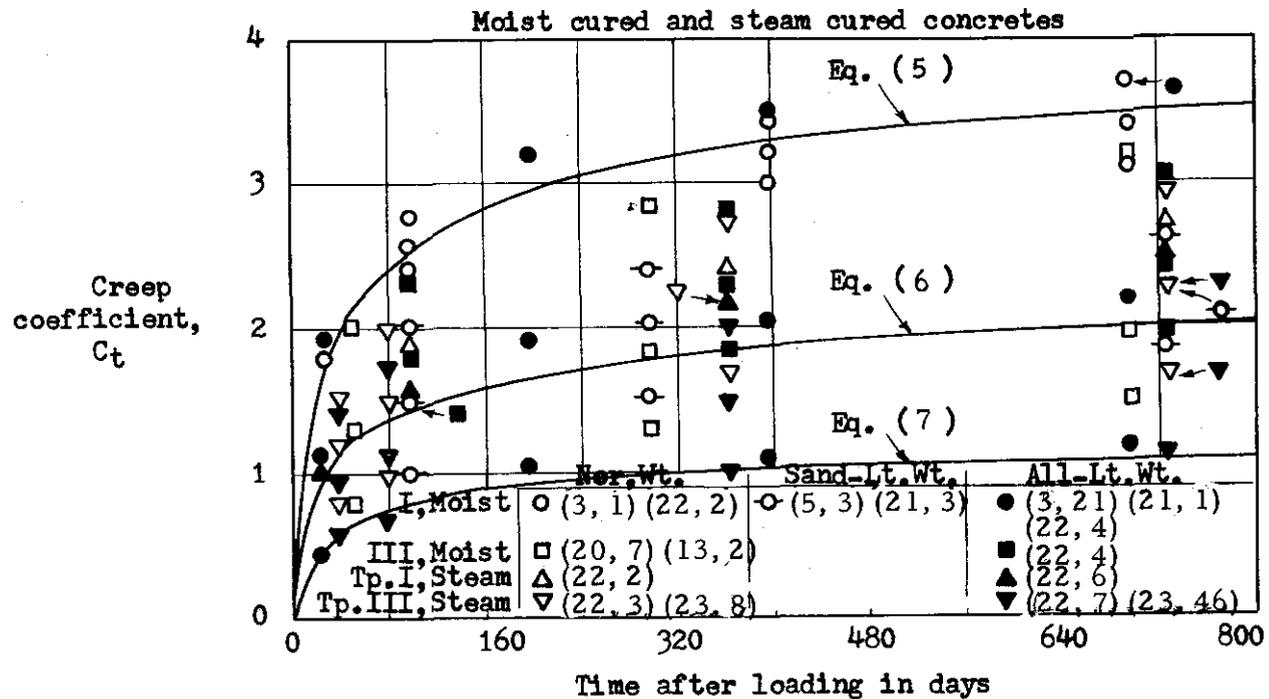

Fig. 5--Standard creep coefficient equation, Eq. (6), and upper and lower-limit curves compared with data. In each set of parentheses, the first and second numbers, respectively, refer to the source of the data and the number of specimens from that source. Three data points shown for a specific time refer to the upper and lower limits and the average value for the data. Where only one data point is shown, the range is too small to indicate. The standard conditions are 3" or less slump, 40% ambient relative humidity, and loading ages of 7 days for moist cured and 2-3 days for steam cured concretes

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 4.07 \quad (8)$$

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 2.75 \quad (9)$$

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 1.98 \quad (10)$$

For the sand-lightweight data, the upper-limit, average-value, and lower-limit curves are defined by:

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 2.97 \quad (11)$$

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 2.00 \quad (12)$$

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 1.35 \quad (13)$$

Similarly, the upper-limit, average-value, and lower-limit curves for the all-lightweight concrete are:

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 4.15 \quad (14)$$

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 2.30 \quad (15)$$

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad 1.30 \quad (16)$$

Therefore Eq. 9, 12, and 15 represent average value general prediction equations for normal weight, sand lightweight and all lightweight concrete respectively.

2.2 Correction Factors for Creep

It has already been indicated that the equations developed in the previous section are only valid for a fixed set of standard conditions. Therefore correction factors are required to convert creep coefficients obtained from Eq. 5 thru 16 to valid predictions for other conditions. Such correction factors are presented for the following parameters.

1. Ambient relative humidity
2. Age when loaded
3. Minimum thickness of member
4. Slump
5. Percent fines
6. Cement content
7. Air content

The correction factors were determined from test data for which the only variable was the parameter under consideration. Relative creep coefficients for specimens tested under other than standard conditions were obtained by dividing the observed values by the creep coefficients obtained from specimens tested under standard conditions.

These relative values were then plotted vs the parameters under consideration and a curve fit to the data.

The effect of ambient relative humidity is shown in Fig. 6. It is suggested no correction factor be used when the humidity is less than 40%, but when the humidity is greater than 40%, use Eq. (17) to obtain the correction factor.

$$\text{Creep (C.F.)}_H = 1.27 - 0.0067H \quad \text{for } H \geq 40\% \quad (17)$$

where H is the ambient relative humidity in percent.

Fig. 7 indicates the effect of age when loaded on creep coefficients for moist cured and steam cured concretes. The average curves are suggested for use as creep coefficient correction factors. For moist and steam cured concretes, respectively, these average curves are closely approximated by the following equations:

$$\text{Creep (C.F.)}_{LA} = 1.25(t)^{-0.118} \quad \text{for moist cured} \quad (18)$$

$$\text{Creep (C.F.)}_{LA} = 1.13(t)^{-0.095} \quad \text{for steam cured} \quad (19)$$

where t is the loading age in days.

The effect of the minimum thickness of a member, as shown in Fig. 8, tends to decrease as the age of the concrete increases. This indicates the ultimate creep coefficient of a larger member approaches that of a smaller member, though the ultimate creep coefficient of a small member is attained sooner than that of a larger member. The average effect of minimum thickness is given by Eq. (20).

$$\text{Creep (C.F.)}_T = 1.12 - 0.02T \quad (20)$$

where T is the minimum thickness in inches.

Eq. (21) is recommended for use in obtaining correction factors for the effect of slump on creep coefficient.

$$\text{Creep (C.F.)}_S = 0.82 + 0.067S \quad (21)$$

where S is the observed slump in inches. Eq. (21) is plotted with the experimental data in Fig. 9.

Creep coefficient correction factors for the effect of percent fines are given by Eq. (22), which is plotted in Fig. 10.

$$\text{Creep (C.F.)}_F = 0.88 + 0.0024F \quad (22)$$

where F is the ratio of fine aggregate to total aggregate (by weight) expressed as a percentage.

As shown in Fig. 11, an increase in cement content causes a reduced creep strain. However data indicates a proportional increase in modulus of elasticity accompanies an increase in cement content. Thus, cement content has a negligible effect on creep coefficient. The data plotted in Fig. 12 confirms this observation.

Eq. (23), which gives correction factors for the effect of air content on creep coefficient, is illustrated in Fig. 13. The data indicate little effect for air contents less than 6%. Thus, Eq. (23) is to be used for air contents greater than 6%, and no correction factors for air contents less than 6%.

$$\text{Creep (C.F.)}_A = 0.46 + 0.09A \quad \text{for } A \geq 6\% \quad (23)$$

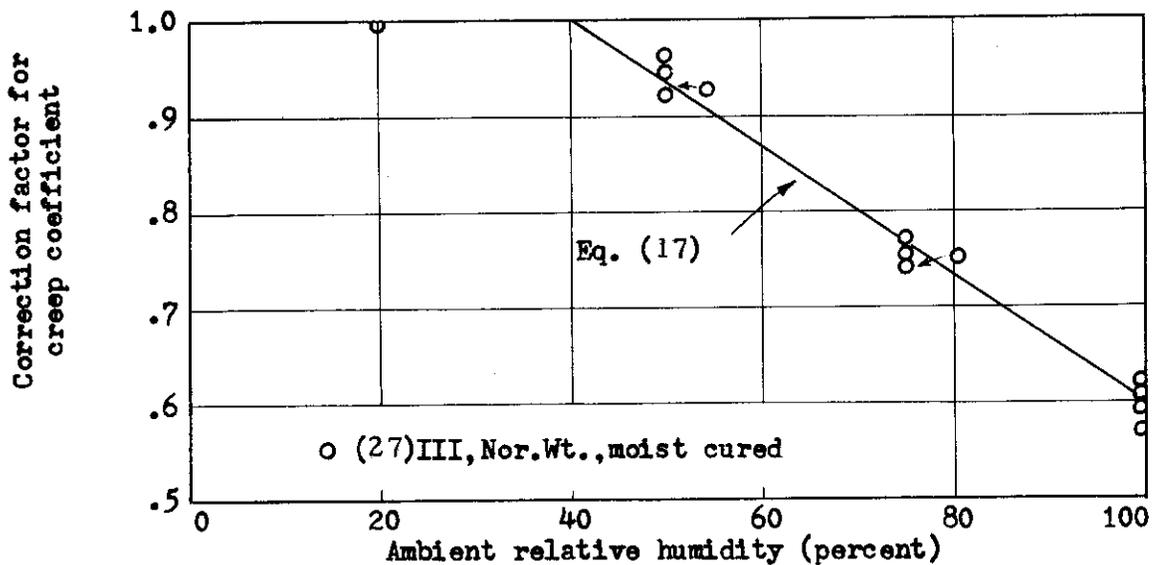

Fig. 6--Creep coefficient correction factors for humidity, with source of data, type of cement, weight classification, and curing technique indicated

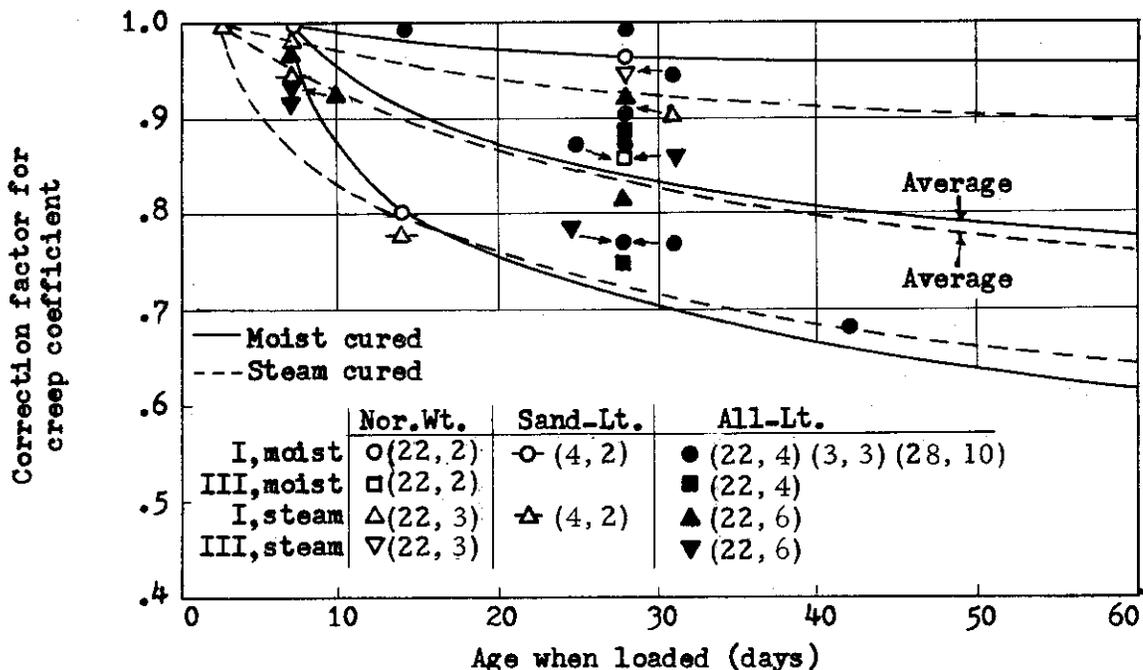

Fig. 7--Creep coefficient correction factors for age when loaded. The first and second numbers in each set of parentheses, respectively, indicate the source of the data and the number of specimens. Average and limit curves are shown for moist and steam cured concretes

where A is the air content in percent.

Further comments on these correction factors are presented in Chapter 3.

2.3 Shrinkage of Concrete

It has been demonstrated that the shrinkage of a concrete specimen with the fixed mix parameters and storage conditions can be predicted with reasonable accuracy using an equation based on the form given in Eq. (2)^(4,5). The shrinkage of specimens subject to other conditions can be estimated using correction factors (see Section 2.4).

Techniques similar to those utilized in the development of the creep prediction equations were used to develop Eq. (24) and (25). These equations were derived from the data shown in Figs. 14 and 15. The standard conditions for these and subsequent shrinkage equations are 3" or less slump, 40% ambient relative humidity, minimum thickness of member 6" or less, and shrinkage considered from 7 days for moist cured concrete and from 2 to 3 days for steam cured concrete.

$$(\epsilon_{sh})_t = \frac{t}{35 + t} (\epsilon_{sh})_u \quad \text{for moist cured} \quad (24)$$

$$(\epsilon_{sh})_t = \frac{t}{55 + t} (\epsilon_{sh})_u \quad \text{for steam cured} \quad (25)$$

The actual shrinkage strains for moist cured concrete are plotted versus time in Fig. 16, and the steam cured concrete data in

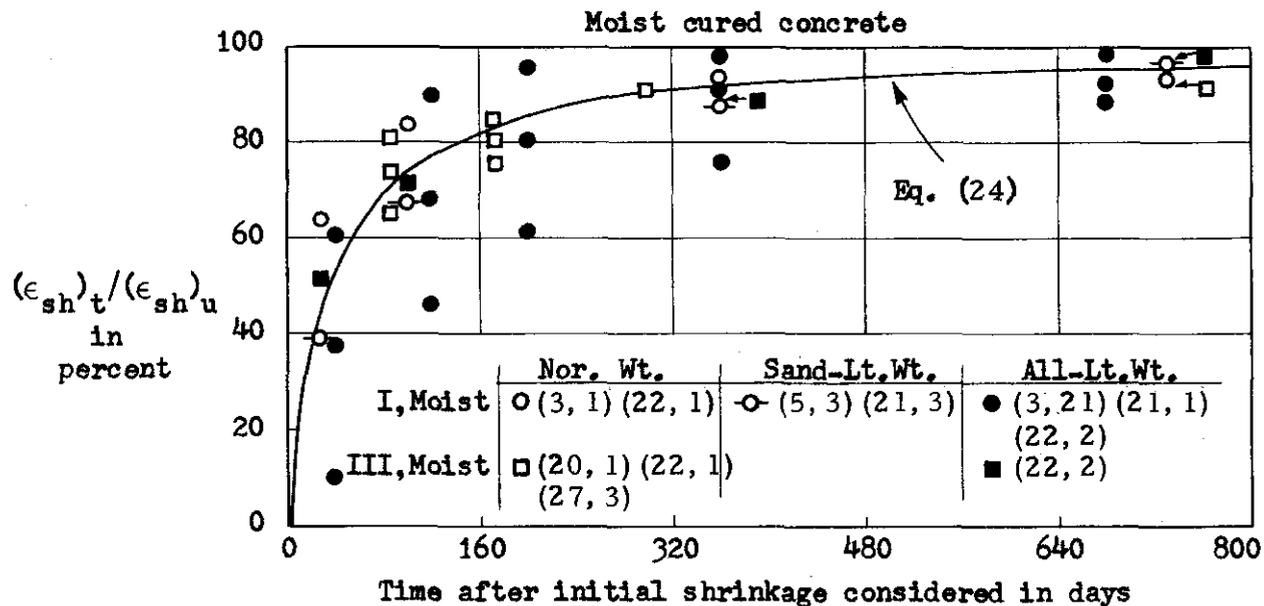

Fig. 14--Shrinkage (considered from 7 days) in percent of ultimate shrinkage versus time curve using Eq. (24) for moist cured concrete, and comparison with data. In each set of parentheses, the first and second numbers, respectively, refer to the source of the data and the number of specimens from that source. Three data points shown for a specific time refer to the upper and lower limits and the average value. Where only one data point is shown, the range is too small to indicate

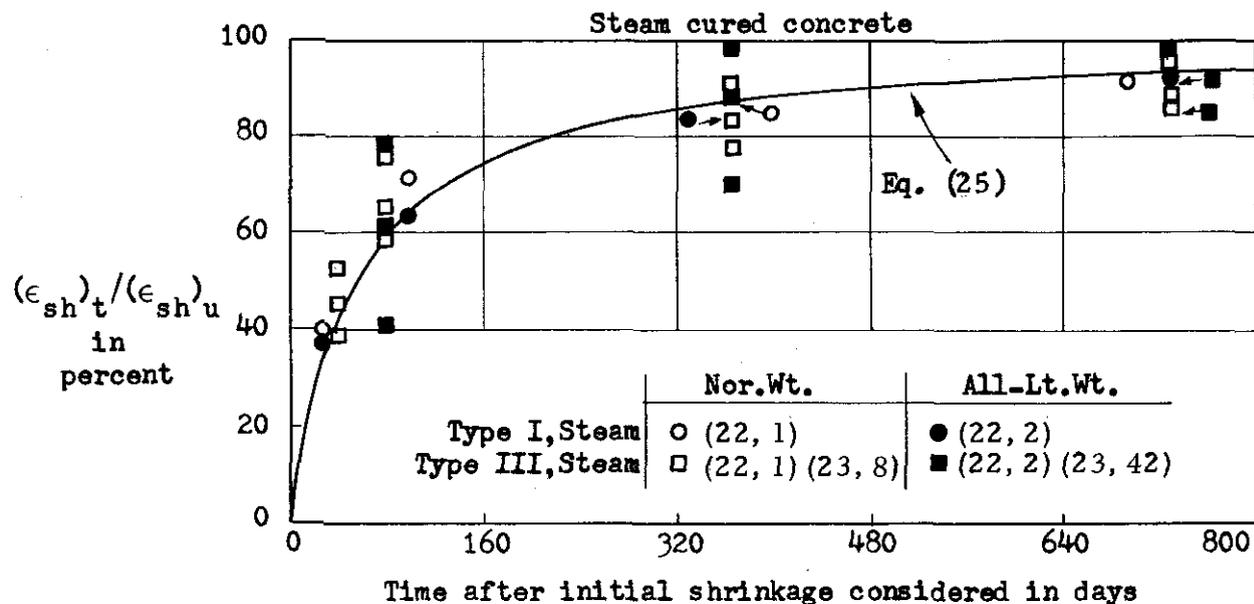

Fig. 15--Shrinkage (considered from 2-3 days) in percent of ultimate shrinkage versus time curve using Eq. (25) for steam cured concrete, and comparison with data. In each set of parentheses, the first and second numbers, respectively, refer to the source of the data and the number of specimens from that source. Three data points shown for a specific time refer to the upper and lower limits and the average value. Where only one data point is shown, the range is too small to indicate

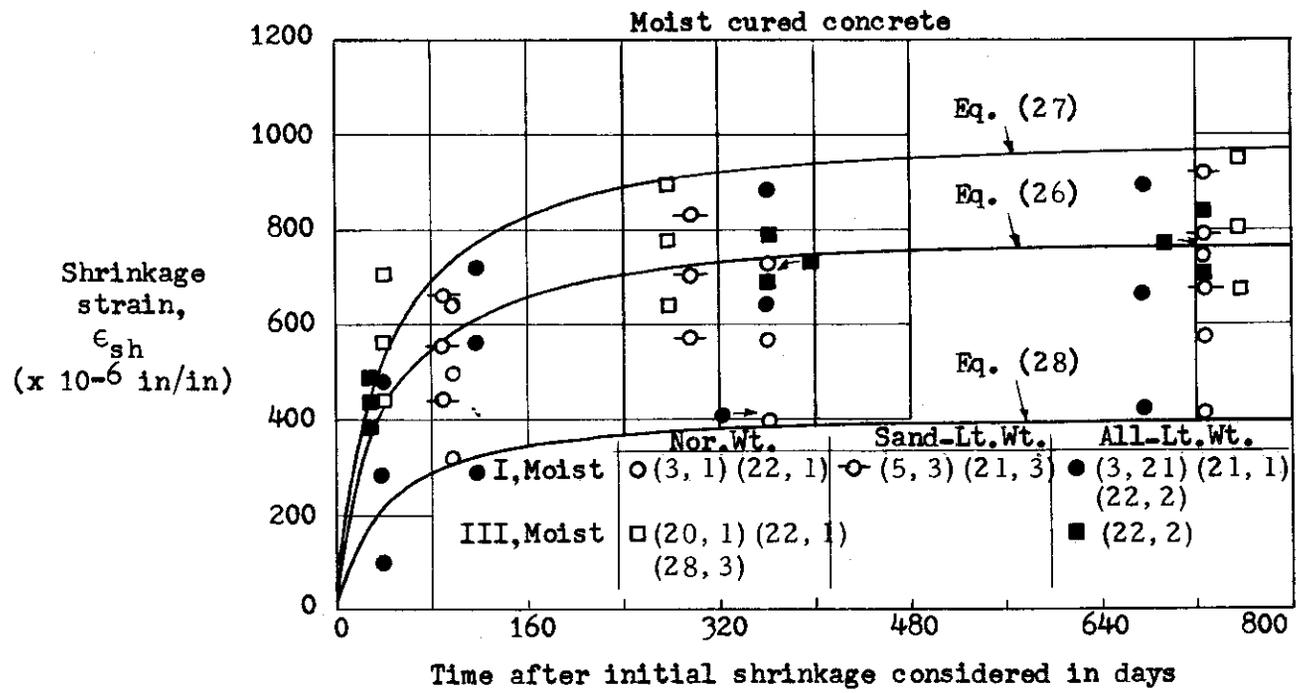

Fig. 16--Shrinkage versus time curve using Eq. (26) and upper and lower-limit curves for moist cured concrete compared with data. In each set of parentheses, the first and second numbers, respectively, refer to the source of the data and the number of specimens from that source. Three data points shown for a specific time refer to the upper and lower limits and the average value. Where only one data point is shown, the range is too small to indicate. The standard conditions are 3" or less slump, 40% ambient relative humidity, minimum thickness of member 6" or less, and shrinkage considered after age 7 days

Fig. 17. The significance of the data points is the same as the interpretation of the standardized creep data in Fig. 5. The average-value and upper- and lower-limit curves for the data are also plotted in Figs. 16 and 17. The average-value curves were obtained in the same manner as was the standard creep equation (Eq. (6)).

Normal ranges of the constants in Eq. (1) for normal weight, sand-lightweight, and all-lightweight concretes (using both moist and steam curing, and types I and III cements) for the data in Figs. 10 and 17 are: $e = 1$, $f = 10$ to 130 , $(\epsilon_{sh})_u = 415$ to 1070×10^{-6} in/in.

Eq. (26) represents the average-value curve for the moist cured concrete data plotted in Fig. 16, and is recommended for predicting shrinkage at any time for moist cured normal weight, sand-lightweight, and all-lightweight concretes. The ultimate value of 800×10^{-6} in/in should be used, however, only in the absence of specific shrinkage data for local aggregates and conditions.

$$(\epsilon_{sh})_t = \frac{t}{35 + t} 800 \times 10^{-6} \text{ in/in} \quad (26)$$

The upper- and lower-limit curves, respectively, are defined by:

$$(\epsilon_{sh})_t = \frac{t}{35 + t} 1010 \times 10^{-6} \text{ in/in} \quad (27)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} 415 \times 10^{-6} \text{ in/in} \quad (28)$$

For the moist cured, normal weight concrete data, the upper-limit, average-value, and lower-limit curves, respectively, are

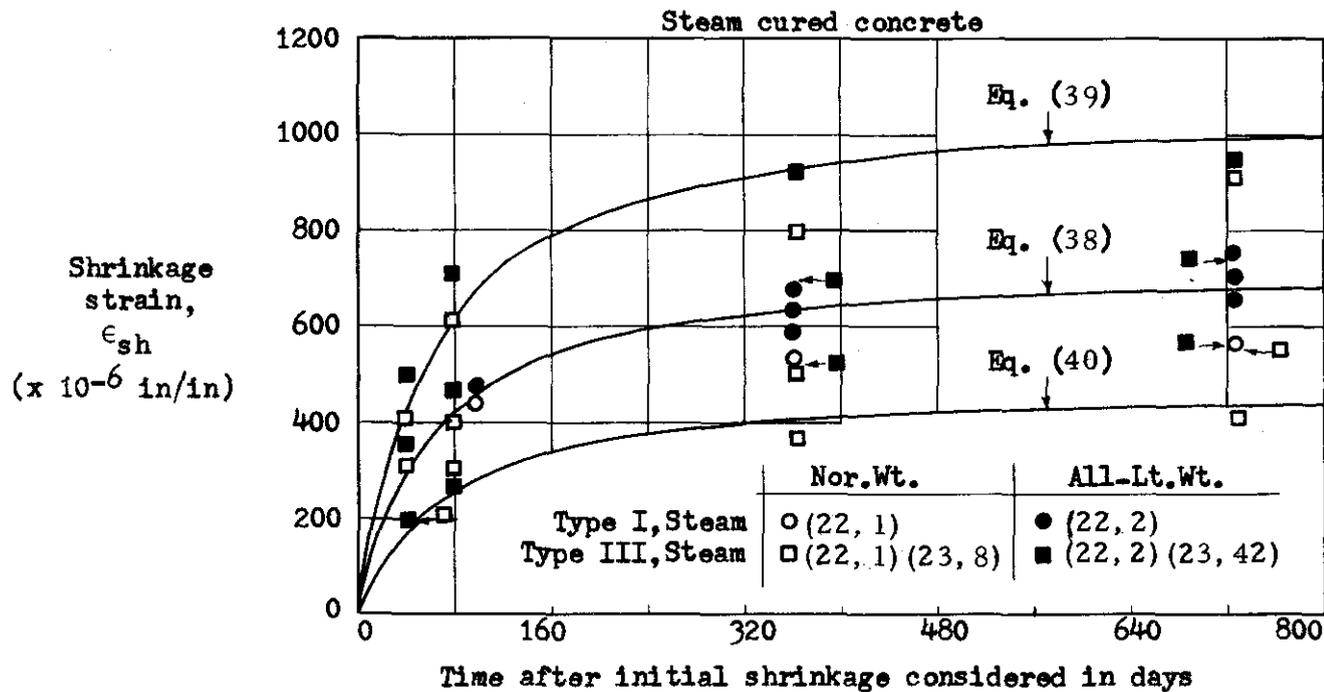

Fig. 17--Shrinkage versus time curve using Eq. (38) and upper and lower-limit curves for steam cured concrete compared with data. In each set of parentheses, the first and second numbers, respectively, refer to the source of the data and the number of specimens from that source. Three data points shown for a specific time refer to the upper and lower limits and the average value. Where only one data point is shown, the range is too small to indicate. The standard conditions are 3" or less slump, 40% ambient relative humidity, minimum thickness of member 6" or less, and shrinkage considered after age 2-3 days

given by:

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 1000 \times 10^{-6} \text{ in/in} \quad (29)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 825 \times 10^{-6} \text{ in/in} \quad (30)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 415 \times 10^{-6} \text{ in/in} \quad (31)$$

For the moist cured, sand-lightweight data, the upper-limit, average-value, and lower-limit curves are defined by:

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 965 \times 10^{-6} \text{ in/in} \quad (32)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 785 \times 10^{-6} \text{ in/in} \quad (33)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 620 \times 10^{-6} \text{ in/in} \quad (34)$$

Similarly, the upper-limit, average-value, and lower-limit curves for the moist cured, all-lightweight concrete data are:

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 1010 \times 10^{-6} \text{ in/in} \quad (35)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 800 \times 10^{-6} \text{ in/in} \quad (36)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} \quad 435 \times 10^{-6} \text{ in/in} \quad (37)$$

Eqs. (30), (33), and (36) indicate very little difference between the ultimate shrinkage values of normal weight, sand-lightweight, and all-lightweight concretes. The numbers of specimens for each of the

different weight concretes are unequal, however. Seven normal weight, six sand-lightweight, and twenty-six all-lightweight specimens were considered. Thus, it is difficult to draw conclusions about relative ultimate shrinkage strains for the different weight concretes.

It is felt, however, the average ultimate shrinkage $((\epsilon_{sh})_u = 800 \times 10^{-6}$ in/in), as used in Eq. (26), represents the average conditions quite accurately. The overall numerical average of $(\epsilon_{sh})_u$ for all the data is 803×10^{-6} in/in.

Eq. (38) represents the average-value curve for the steam cured concrete data plotted in Fig. 17, and is recommended for use as a standard shrinkage equation for all steam cured concretes. The ultimate value of 730×10^{-6} in/in should be used, however, only in the absence of specific shrinkage data for local aggregates and conditions.

$$(\epsilon_{sh})_t = \frac{t}{55 + t} 730 \times 10^{-6} \text{ in/in} \quad (38)$$

The upper- and lower-limit curves plotted in Fig. 17, respectively, are defined by:

$$(\epsilon_{sh})_t = \frac{t}{55 + t} 1070 \times 10^{-6} \text{ in/in} \quad (39)$$

$$(\epsilon_{sh})_t = \frac{t}{55 + t} 470 \times 10^{-6} \text{ in/in} \quad (40)$$

For the steam cured, normal weight concrete data, the upper-limit, average-value, and lower-limit curves, respectively, are given by:

$$(\epsilon_{sh})_t = \frac{t}{55 + t} \quad 1050 \times 10^{-6} \text{ in/in} \quad (41)$$

$$(\epsilon_{sh})_t = \frac{t}{55 + t} \quad 640 \times 10^{-6} \text{ in/in} \quad (42)$$

$$(\epsilon_{sh})_t = \frac{t}{55 + t} \quad 470 \times 10^{-6} \text{ in/in} \quad (43)$$

Similarly, the upper-limit, average-value, and lower-limit curves for the steam cured, all-lightweight concrete data are:

$$(\epsilon_{sh})_t = \frac{t}{55 + t} \quad 1070 \times 10^{-6} \text{ in/in} \quad (44)$$

$$(\epsilon_{sh})_t = \frac{t}{55 + t} \quad 820 \times 10^{-6} \text{ in/in} \quad (45)$$

$$(\epsilon_{sh})_t = \frac{t}{55 + t} \quad 630 \times 10^{-6} \text{ in/in} \quad (46)$$

Although Eqs. (42) and (45) indicate the ultimate shrinkage of steam cured, lightweight concrete is greater than that of steam cured, normal weight concrete, the amount of lightweight concrete data analyzed is considerably more than the amount of normal weight concrete data. Ten normal weight and forty-six all-lightweight specimens were considered. Thus, it is difficult to draw conclusions about the relative ultimate shrinkage strains of the different weight concretes.

It is felt, however, the average ultimate shrinkage $((\epsilon_{sh})_u = 730 \times 10^{-6} \text{ in/in})$, as used in Eq. (38), represents the average conditions quite accurately. The overall numerical average of $(\epsilon_{sh})_u$ for all the data is $788 \times 10^{-6} \text{ in/in}$.

A comparison of Eqs. (26) and (38) indicates steam cured concretes experience slightly smaller shrinkage strains than moist cured concretes.

2.4 Factors Influence Shrinkage

Correction factors for the effects of the following parameters on shrinkage of moist and steam cured concretes are developed in this section:

1. Ambient relative humidity
2. Age from which shrinkage is considered
3. Minimum thickness of member
4. Slump
5. Percent fines
6. Cement content
7. Air content

These correction factors are to be applied to values given by Eq. (26) or Eq. (38), respectively, depending on whether the concrete is moist cured or steam cured, to correct data for conditions other than the standard conditions. The correction factors developed herein are derived in the same manner as are the creep correction factors developed in Section 2.2 of this report.

The effect of ambient relative humidity is shown in Fig. 18, an analysis of which indicates no correction factor is required when the humidity is less than 40%. When the humidity is greater than 40%

use either Eq. (47a) or Eq. (47b), depending upon within which range the humidity falls.

$$\text{Shrinkage (C.F.)}_H = 1.40 - 0.01H \quad (47a)$$

$$\underline{\text{for } 40\% = H = 80\%}$$

$$\text{Shrinkage (C.F.)}_H = 3.00 - 0.03H \quad (47b)$$

$$\underline{\text{for } 80\% = H = 100\%}$$

where H is the ambient relative humidity in percent.

For shrinkage considered from later than 7 days for moist cured concrete, first determine the standard shrinkage value for any time using Eq. (26). Next, compute the shrinkage occurring between 7 days and the age from which shrinkage is desired, again using Eq. (26). Thus, the shrinkage occurring after a certain age is merely the shrinkage considered from 7 days less the shrinkage occurring between 7 days and the age from which shrinkage predictions are desired. A similar procedure is suggested for steam cured concrete, using Eq. (38) and considering shrinkage from 2-3 days.

For shrinkage of moist cured concrete from 1 day, a correction factor of 1.20 is proposed to correct the standard value given by Eq. (26). The basis of this correction factor is presented in Fig. 19. For shrinkage of moist cured concrete from between 1 day and 7 days, linearly interpolate between correction factors of 1.20 for 1 day and 1.00 for 7 days.

The effect of the minimum thickness of a member, as shown in Fig. 20, decreases as the age of the concrete increases. Thus,

the ultimate shrinkage of a large member approaches that of a smaller member, though the ultimate shrinkage of a small member is reached sooner than that of a larger member. The average effect of minimum thickness is given by Eq. (48).

$$\text{Shrinkage (C.F.)}_T = 1.193 - 0.0322T \quad (48)$$

where T is the minimum thickness in inches.

Eq. (49) is recommended for obtaining correction factors for the effect of slump on shrinkage.

$$\text{Shrinkage (C.F.)}_S = 0.89 + 0.0407S \quad (49)$$

where S is the slump in inches. Eq. (49) is plotted with experimental data in Fig. 21.

Shrinkage correction factors for the effect of percent fines are given by Eqs. (50a) and (50b), which are plotted in Fig. 22.

$$\text{Shrinkage (C.F.)}_F = 0.30 + 0.014F \quad (50a)$$

for F = 50%

$$\text{Shrinkage (C.F.)}_F = 0.90 + 0.002F \quad (50b)$$

for F = 50%

where F is the percent of fine aggregate by weight.

As shown in Fig. 23, a variation in cement content has a considerable affect on shrinkage. The shrinkage correction factors for cement content are given by Eq. (51).

$$\text{Shrinkage (C.F.)}_B = 0.75 + 0.034B \quad (51)$$

where B is the number of bags of cement per cubic yard.

Eq. (52), which gives shrinkage correction factors for the effect of air content, is plotted with observed data in Fig. 24.

$$\text{Shrinkage (C.F.)}_A = 0.95 + 0.008A \quad (52)$$

where A is the air content in percent.

Chapter 3

SUMMARY AND EXAMPLE OF CREEP AND SHRINKAGE
PREDICTION METHODS

The equations and procedures developed in Chapter II are simple to apply and in some cases can be further simplified. In this chapter two example predictions will be illustrated and the results compared to observed values. In addition, a simplified prediction method will be presented.

3.1 Summary of General Prediction Methods

Standard creep equation -- 3" or less slump, 40% ambient relative humidity, loading age 7 days for moist cured and 2-3 days for steam cured concrete

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \cdot 2.35 \quad (6)$$

Creep correction factors

Ambient relative humidity:

$$\text{Creep (C.F.)}_H = 1.27 - 0.0067H \quad (17)$$

for H = 40%

Loading age:

$$\text{Creep (C.F.)}_{LA} = 1.25 (t)^{-0.118} \quad (18)$$

for moist cured

$$\text{Creep (C.F.)}_{LA} = 1.13 (t)^{-0.095} \quad (19)$$

for steam cured

Minimum thickness of member:

$$\text{Creep (C.F.)}_T = 1.12 - 0.02T \quad (20)$$

Slump:

$$\text{Creep (C.F.)}_S = 0.82 + 0.067S \quad (21)$$

Percent fines:

$$\text{Creep (C.F.)}_F = 0.88 + 0.0024F \quad (22)$$

Cement content:

No correction factors required.

Air content:

$$\text{Creep (C.F.)}_A = 0.46 + 0.09A \quad (23)$$

for A = 6%

Standard shrinkage equations -- 3" or less slump, 40% ambient relative humidity, minimum thickness of member 6" or less

Shrinkage after age 7 days for moist cured concrete

$$(\epsilon_{sh})_t = \frac{t}{35 + t} 800 \times 10^{-6} \text{ in/in} \quad (26)$$

Shrinkage after age 2-3 days for steam cured concrete

$$(\epsilon_{sh})_t = \frac{t}{55 + t} 730 \times 10^{-6} \text{ in/in} \quad (38)$$

Shrinkage correction factors

Ambient relative humidity:

$$\text{Shrinkage (C.F.)}_H = 1.40 - 0.01H \quad (47a)$$

for 40% = H = 80%

$$\text{Shrinkage (C. F.)}_H = 3.00 - 0.03H \quad (47b)$$

for 80% = H = 100%

Age from which shrinkage is considered:

For shrinkage considered from later than 7 days for moist cured concrete and later than 2-3 days for steam cured concrete, respectively, determine the differential in Eqs. (26) and (38) for any period starting after this time. For shrinkage of moist cured concrete from 1 day, use Shrinkage (C. F.) = 1.20.

Minimum thickness of member:

$$\text{Shrinkage (C. F.)}_T = 1.193 - 0.0322T \quad (48)$$

Slump:

$$\text{Shrinkage (C. F.)}_S = 0.89 + 0.0407S \quad (49)$$

Percent fines:

$$\text{Shrinkage (C. F.)}_F = 0.30 + 0.014F \quad (50a)$$

for F = 50%

$$\text{Shrinkage (C. F.)}_F = 0.90 + 0.002F \quad (50b)$$

for F = 50%

Cement content:

$$\text{Shrinkage (C. F.)}_B = 0.75 + 0.034B \quad (51)$$

Air content:

$$\text{Shrinkage (C. F.)}_A = 0.95 + 0.008A \quad (52)$$

3.2 Design Example No. 1 Using General Prediction Method

Specimen reference (22) 10N6

Moist cured concrete, lightweight

50% ambient relative humidity

Shrinkage considered from 7 days

Minimum thickness of member 8 inches

Loaded at 6 days of age

2.3 inches of slump

60% fines (assumed)

7.7 bags of cement per cubic yard

6.5% air content

Standard values:

$$C_{365} = \frac{365^{0.60}}{10 + 365^{0.60}} \quad 2.35 = \frac{34.3}{44.3} \quad 2.35 = 1.82$$

$$(e_{sh})_{365} = \frac{365}{35 + 365} 800 \times 10^{-6} \text{ in/in} = 730 \times 10^{-6} \text{ in/in}$$

Creep correction factors

$$50\% \text{ humidity} \quad 0.93 \quad (17)$$

$$\text{loaded at 6 days} \quad 1.01 \quad (18)$$

$$8 \text{ in. minimum thickness} \quad 0.96 \quad (20)$$

$$2.3 \text{ inches slump} \quad 0.97 \quad (21)$$

$$60\% \text{ fines} \quad 1.02 \quad (22)$$

$$6.5\% \text{ air content} \quad 1.06 \quad (23)$$

Shrinkage correction factors

$$50\% \text{ humidity} \quad 0.90 \quad (47a)$$

$$\text{shrinkage from 7 days} \quad 1.00$$

$$8 \text{ in. minimum thickness} \quad 0.94 \quad (48)$$

2.3 inches slump 0.94 (49)

60% fines 1.02 (50)

7.7 bags of cement 1.01 (51)

6.5% air content 1.00 (52)

The desired creep and shrinkage values for one year are then obtained by multiplying the standard values by the respective set of correction factors.

$$C_{365} = (1.82) (0.93 \times 1.01 \times 0.96 \times 0.97 \times 1.02 \times 1.06) = \underline{1.72}$$

Experimental C_{365} from data is 1.79.

$$(\epsilon_{sh})_{365} = (730 \times 10^{-6} \text{ in/in})(0.90 \times 1.00 \times 0.94 \times 0.94 \times 1.02 \times 1.01 \times 1.00) = \underline{596 \times 10^{-6} \text{ in/in}}$$

Experimental $(\epsilon_{sh})_{365}$ from data is $660 \times 10^{-6} \text{ in/in}$.

3.3 Design Example No. 2 Using General Prediction Method

Specimen reference (22) 6R2

Steam cured concrete, lightweight

50% ambient relative humidity

Shrinkage considered from 7 days

Minimum thickness of member 8 inches

Loaded at 2 days of age

2.5 inches of slump

60% fines (assumed)

8.8 bags of cement per cubic yard

6.1% air content

Standard values

$$C_{365} = \frac{365^{0.60}}{10 + 365^{0.60}} \quad 2.35 = \frac{34.3}{44.3} \quad 2.35 = 1.82$$

$$(\epsilon_{sh})_{365} = \frac{365}{55 + 365} \quad 730 \times 10^{-6} \text{ in/in} = 365 \times 10^{-6} \text{ in/in}$$

Creep correction factors

50% humidity	0.93	(17)
Loaded at 2 days	1.06	(19)
8 in. minimum thickness	0.96	(20)
2.5 inches slump	0.99	(21)
60% fines	1.02	(22)
6.1% air content	1.01	(23)

Shrinkage correction factors

50% humidity	0.90	(47a)
Shrinkage from 7 days	1.00	
8 in. minimum thickness	0.94	(48)
2.5 inches slump	0.99	(49)
60% fines	1.02	(50)
8.8 bags of cement	1.05	(51)
6.1% air content	1.00	(52)

The desired creep and shrinkage values for one year are then obtained by multiplying the standard values by the respective set of

correction factors.

$$C_{365} = (1.82)(0.93 \times 1.06 \times 0.96 \times 0.99 \times 1.02 \times 1.01) = \underline{1.76}$$

Experimental C_{365} from data is 1.80.

$$(\epsilon_{sh})_{365} = (365 \times 10^{-6} \text{ in/in})(0.90 \times 1.00 \times 0.94 \times 0.99 \times 1.02 \times 1.05 \times 1.00) = \underline{570 \times 10^{-6} \text{ in/in}}$$

Experimental $(\epsilon_{sh})_{365}$ from data is $595 \times 10^{-6} \text{ in/in}$

3.4 Summary of a Simplified Prediction Method

Quite often, the effects of many variables on creep and shrinkage are not excessive and tend to offset each other. These may normally be neglected in design calculations. The following summary and comments form the basis of a simplified prediction method.

Creep correction factors

Minimum thickness of member: C.F. = 0.96 for 8", 0.88 for 12".

Comment--Tends to be offset by high slumps, probably negligible in most cases.

Slump: C.F. = 0.95 for 2", 1.00 for 2.7", 1.09 for 4".

Comment--Negligible for slumps below 5".

Percent fines (by wt.): C.F. = 0.72 for 30%, 1.00 for 50%, 1.04 for 70%. Comment--Negligible for percent fines less than 45%.

Cement content (bags/cu.yd.): C.F. = 0.87 for 4 bags, 0.95 for 6 bags, 1.00 for 7.5 bags, 1.09 for 10 bags. Comment--Normally negligible.

Air content (in %): C.F. = 0.98 for 4%, 1.00 for 6%, 1.03 for 10%. Comment--Negligible.

Therefore, in a simplified design procedure, the only variables for which corrections must be made are humidity, age when loaded, and age from which shrinkage is considered. A simplified design procedure should be used, however, only when the comments in the above

summary are applicable. For example, for large structures (minimum thickness greater than 12", for example), correction factors for member size for creep and especially shrinkage should be considered.

3.5 Design Example No. 1 Using Simplified Prediction Method

Standard Values

$$C_{365} = 1.82$$

$$(\epsilon_{sh})_{365} = 730 \times 10^{-6} \text{ in/in}$$

Creep Correction Factors

$$50\% \text{ humidity} \qquad 0.93 \qquad (17)$$

$$\text{Loaded at 6 days} \qquad 1.01 \qquad (18)$$

Shrinkage Correction Factors

$$50\% \text{ humidity} \qquad 0.90 \qquad (47a)$$

$$\text{Shrinkage from 7 days} \qquad 1.00$$

Modified Creep and Shrinkage Values

$$C_{365} = 1.82 (.93)(1.01) = 1.71$$

$$(\epsilon_{sh})_{365} = 730 \times 10^{-6} (.90)(1.00) = 657 \times 10^{-6} \text{ in/in}$$

Experimental Values

$$C_{365} = 1.79$$

$$(\epsilon_{sh})_{365} = 660 \times 10^{-6} \text{ in/in}$$

3.6 Design Example No. 2 Using Simplified Prediction Method

Standard Values

$$C_{365} = 1.82$$

$$(\epsilon_{sh})_{365} = 365 \times 10^{-6} \text{ in/in}$$

Creep Correction Factors

$$50\% \text{ humidity} \qquad 0.93 \qquad (17)$$

$$\text{Loaded at 7 days} \qquad 1.06 \qquad (19)$$

Shrinkage Correction Factors

$$50\% \text{ humidity} \qquad 0.90 \qquad (47a)$$

$$\text{Shrinkage from 7 days} \qquad 1.00$$

Modified Creep and Shrinkage Values

$$C_{365} = 1.82 (0.93)(1.06) = 1.79$$

$$(\epsilon_{sh})_{365} = 635 \times 10^{-6} (0.90) = 572 \times 10^{-6} \text{ in/in}$$

Experimental Values

$$C_{365} = 1.80$$

$$(\epsilon_{sh})_{365} = 595$$

3.7 General Remarks on Prediction Methods

It has been shown that the general prediction methods developed in Chapter II can be easily and accurately applied to predict the long-time creep and shrinkage behavior of concrete. In addition, simplified

prediction methods were also shown to yield accurate estimates of time dependent behavior.

Chapter 4

EXPERIMENTAL PROGRAM

In order to independently verify the development of the general prediction methods, the experimental program described below was carried out. In addition, specific prediction equations for concrete mixtures made with the aggregates tested are recommended.

Creep and shrinkage behavior for the following four commercial aggregates were obtained.

Idealite - manufactured by Idealite Co., Denver, Colorado.

Haydite - manufactured by Hydraulic Press Brick Co.,
Brooklyn, Indiana

Haydite - manufactured by Carter-Waters Corp., Kansas
City, Missouri

Haydite - manufactured by Buildex, Inc., Ottawa, Kansas.

4.1 Concrete Mixes and Properties

All tests and test specimens for this investigation were produced in the structures laboratory at the University of Iowa, except for one group of steam cured specimens cast and supplied by Prestressed Concrete of Iowa, Inc.

The concrete mixes listed in Table 1 were designed using specifications for prestressed bridge girders, (i.e., 4,500 psi strength after 7 days moist curing or 2-3 days steam curing and a

28 day strength of 5,000 psi using Type I cement. All mixes used commercially manufactured lightweight artificial aggregate with 100 percent sand substitution for the fine portion of the mix. Table 2 shows the concrete properties that were obtained for the various mixes listed.

4.2 Preparation of Specimens

Preparation of test specimens and performance of tests followed ASTM specifications.⁽²⁴⁾ Test specimens were standard 6 inch diameter by 12 inch long cylinders cast in three layers, each layer rodded 25 strokes. The cylinders were moist cured five days at 100 percent relative humidity. Forms were stripped on the fifth day and the surface was allowed to dry. The ends of each specimen were scrubbed with a wire brush to remove any loose material in preparation for capping. On the sixth day the specimens were capped with a sulfur base capping compound.

Gage points were fastened to the specimens immediately after capping on the sixth day. The gage points consisted of small stainless steel plugs with a shallow hole drilled in one end. Gage points were arranged in three equally spaced rows about the specimen and were securely fastened to the surface by means of epoxy resins. A standard 10-inch gage length bar was used during initial spacing of the gage points. A strip of masking tap tightened over the gage points prevented their sliding during the four hours required for the adhesive to set. The instrumented specimens were then stored in the

TABLE 1 - DETAILS OF CONCRETE MIXES AND MIXING PROCEDURE

Group I-S specimens were steam cured, all others were moist cured

room in which the tests were to be conducted until the time of loading.

4.3 Test Equipment

Compressive strength and modulus of elasticity tests were performed using a Riehle hydraulic testing machine, least count 500 pounds. The sustained load was applied with a hydraulic jack containing a pressure gage, least count 100 pounds. Prior to loading, the jack was calibrated against the testing machine as a standard.

Test specimens were loaded at 7 days and 14 days after casting in standard ASTM type creep racks which consisted of three equally spaced rods through holes in one inch thick steel plates. The sustained load was supplied by three nested coil compression spring units of approximately equal capacity. Figures A1 and A2 in the Appendix illustrate the typical equipment.

Stress-strain data were obtained by an Ames dial gage, least count 0.0001 inches, on a collar apparatus which was attached to a specimen prior to a compressive strength test. Shrinkage and creep data were obtained with a 10-inch Whittemore strain gage, least count 0.0001 inches.

4.4 Data Collection

Three separate specimens were used to determine the compressive strength at each of the 7, 14, and 28 day ages; an average value was then used for each age. Stress-strain data were taken on one specimen during the compressive strength test. Stress-strain

curves for the four concrete mixes listed in Table (1) are shown in Figures 25 - 28.

Shrinkage data for each of the mixes were obtained from three separate specimens, each specimen having three gage lengths; an average of the nine values was then used. Shrinkage specimens were stored in the same environment as the loaded specimens. Creep data for each stress level were obtained from three separate specimens, each specimen having three different gage lengths, thus giving nine values from which an average was determined.

The three specimens under load for each test were stacked vertically in a single creep rack and loaded simultaneously. Care was taken during loading to insure that no significant eccentricity of loading occurred. This was accomplished by checking gage point deformations at about 300 psi, or well within the elastic range, before any further load was applied. If appreciable eccentricity existed the load was removed and the specimens realigned.

Creep and shrinkage data were collected for approximately 200 days after loading (range 168 - 282 days). All data is tabulated in the Appendix. An initial gage length was recorded prior to loading and an elastic deformation was recorded immediately after loading. The value of creep was evaluated as the total deformation of loaded gage length minus the shrinkage value and the initial elastic deformation.

Load checks were performed occasionally and corrections

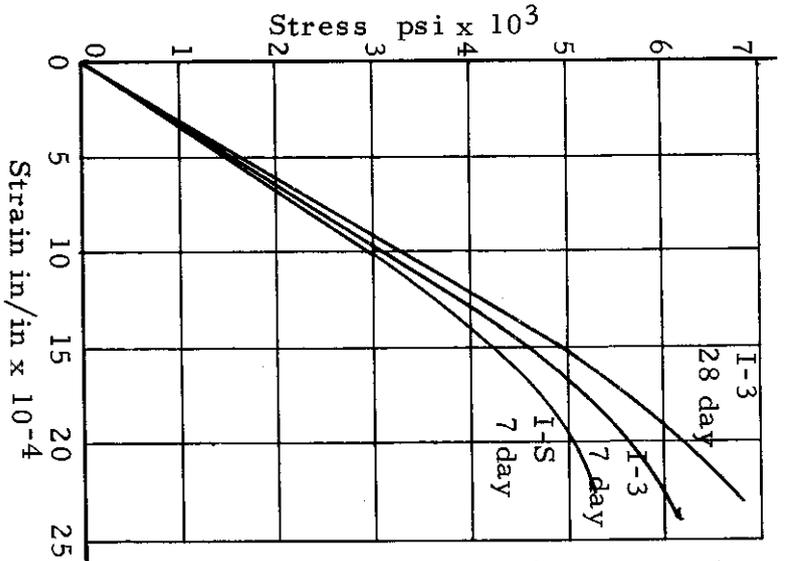

Fig. 25 σ vs. ϵ curve, Mix I-3, I-S

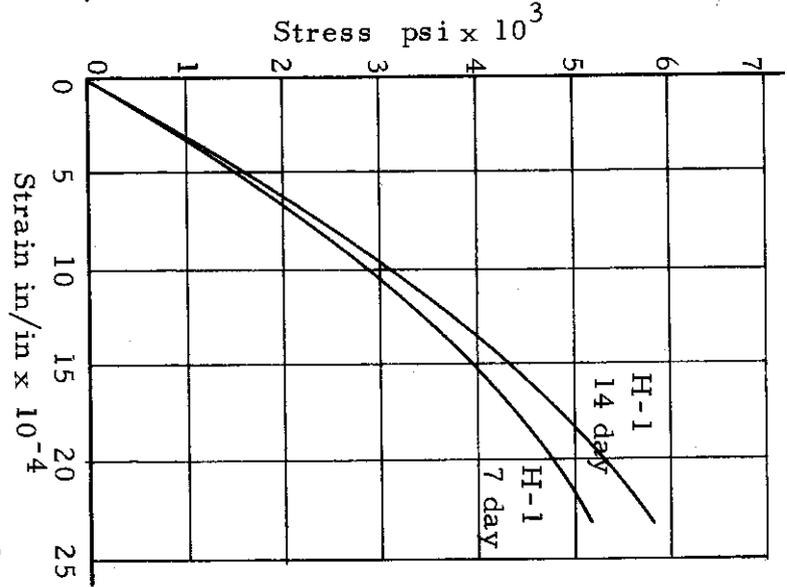

Fig. 26 σ vs. ϵ curve, Mix H-1

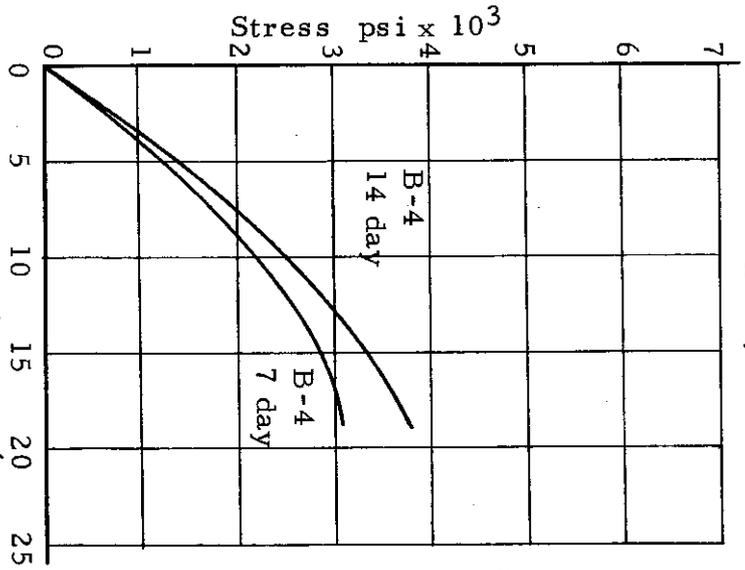

Fig. 27 σ vs. ϵ curve, Mix B-4

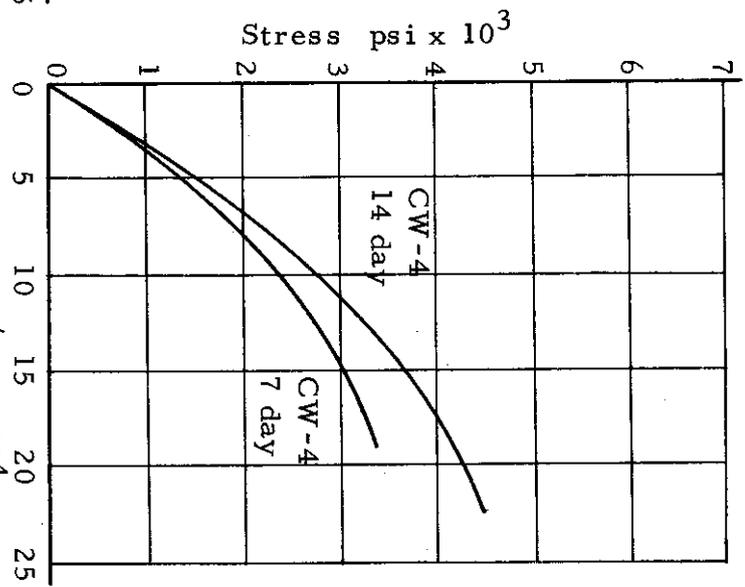

Fig. 28 σ vs. ϵ curve, Mix CW-4

made for any loss of load. At no time was the load allowed to deviate by more than about four percent from the designated stress level.

Temperature and relative humidity were recorded along with each set of creep and shrinkage values. A temperature correction was made by means of the standard steel bar provided with the Whittemore mechanical strain gage. The coefficient of thermal expansion for concrete is nearly equal to that for steel, 0.000065 in/deg. F.

Chapter 5

CREEP AND SHRINKAGE PROPERTIES OF FOUR LIGHTWEIGHT
AGGREGATE CONCRETES

In order to verify the methods suggested in Chapter 2 and in order to develop specific equations that can be used to predict the creep and shrinkage behavior of the materials investigated, the data was analyzed using the general equations suggested by Branson, et al. ⁽⁵⁾ (Eq. (1) and (2)). In Eq. (1) the exponent c was assumed to be 0.6, and d and C_u were determined experimentally. In Eq. (2) the exponent ϵ was assumed to be 1.0, and f and $(\epsilon_{sh})_u$ were determined experimentally. The specific relations developed are compared to the general methods described in Chapter 2.

Since in all cases the duration of the experimental program was finite, methods to determine ultimate creep coefficients and ultimate shrinkage values were assumed as follows.

The ultimate creep coefficient ($C_u = \epsilon_{cu} / \epsilon_i$) is determined from the following well known relationship ⁽¹⁵⁾

$$\epsilon_{cu} = 4/3 (\epsilon_{c-1 \text{ yr}})$$

where $\epsilon_{c-1 \text{ yr}}$ is the creep strain 1 year after loading (extrapolated from approximately 200 day data).

Once C_u is known the constant d can be easily obtained.

Since there is no well established relationship between percent of ultimate shrinkage and time the shrinkage equations were determined by trial and error, solving simultaneously for the ultimate shrinkage strain $(\epsilon_{sh})_u$ and the constant f .

Using these methods the following creep and shrinkage equations were developed for moist cured concrete (Type I cement) loaded at 7 days after casting.

5.1 Haydite - Hydraulic Press Brick Co.

The creep coefficient and shrinkage prediction equations determined from these data are listed below:

$$C_t = \frac{t^{0.60}}{12.4 + t^{0.60}} \quad (2.15) \quad (53)$$

where 2.15 is the ultimate creep coefficient; and

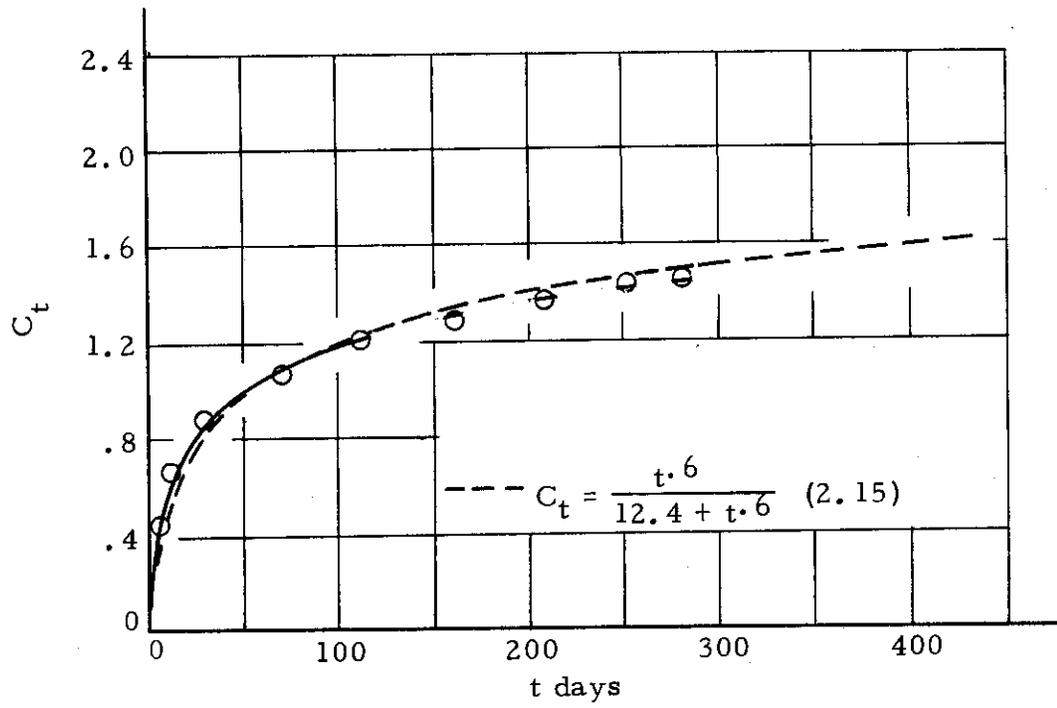

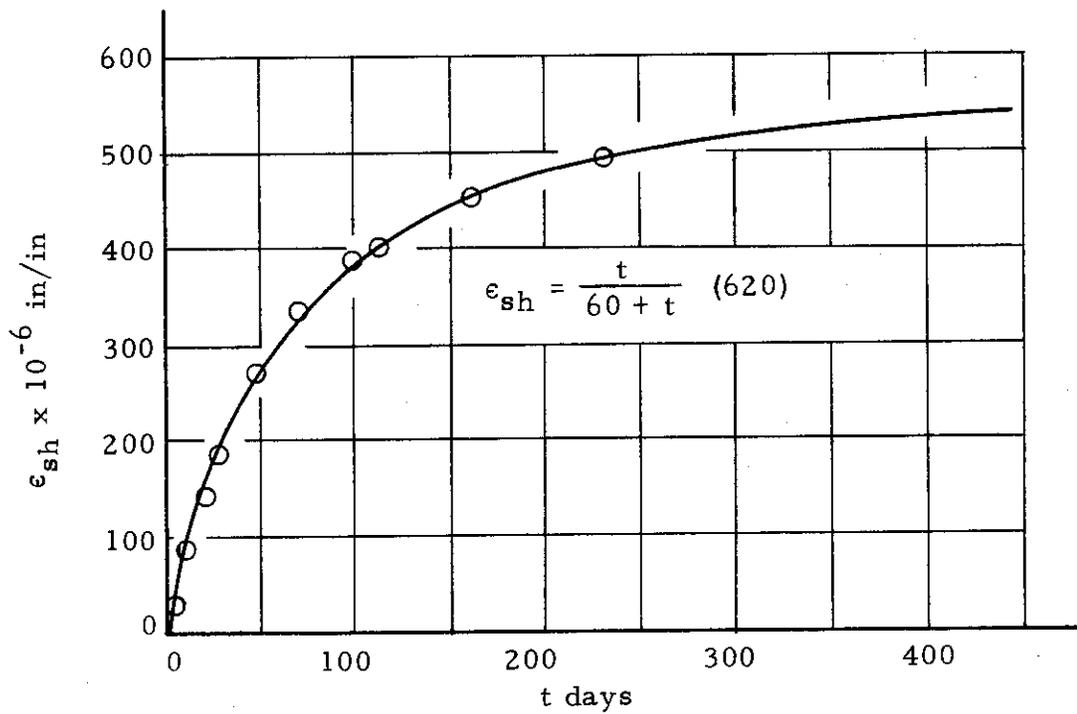

$$\epsilon_{sh} = \frac{t}{60 + t} \quad (620) \quad (54)$$

where 620 is the ultimate shrinkage strain $\times 10^{-6}$ in/in. Figures 29 and 30 show these equations compared with observed data points.

5.2 Haydite - Buildex, Inc.

The creep coefficient and shrinkage prediction equations determined from these data are listed below:

$$C_t = \frac{t^{0.60}}{9.5 + t^{0.60}} \quad (1.95) \quad (55)$$

Fig. 29 C_t vs. t , Mix H-1Fig. 30 ϵ_{sh} vs. t , Mix H-1

where 1.95 is the ultimate creep coefficient; and

$$\epsilon_{sh} = \frac{t}{35 + t} (440) \quad (56)$$

where 440 is the ultimate shrinkage strain $\times 10^{-6}$ in/in. Figures 31 and 32 show these equations compared with observed data points.

5.3 Haydite - The Carter-Waters Corp.

The creep coefficient and shrinkage prediction equations determined from these data are listed below:

$$C_t = \frac{t^{0.60}}{9.7 + t^{0.60}} (2.40) \quad (57)$$

where 2.40 is the ultimate creep coefficient; and

$$\epsilon_{sh} = \frac{t}{35 + t} (590) \quad (58)$$

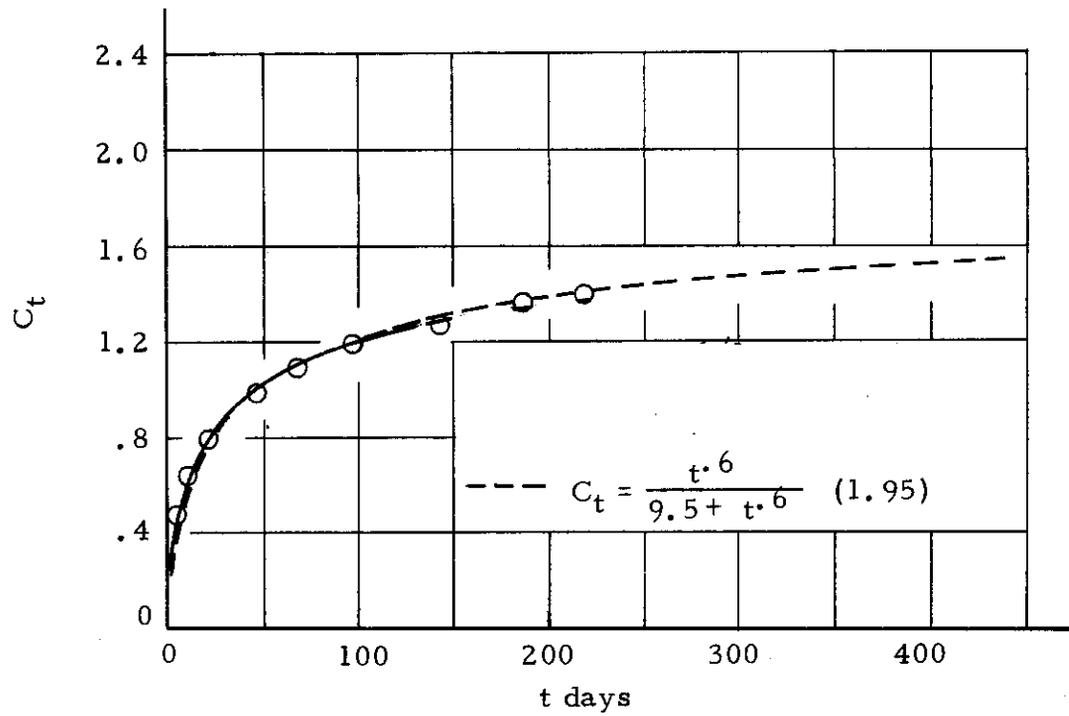

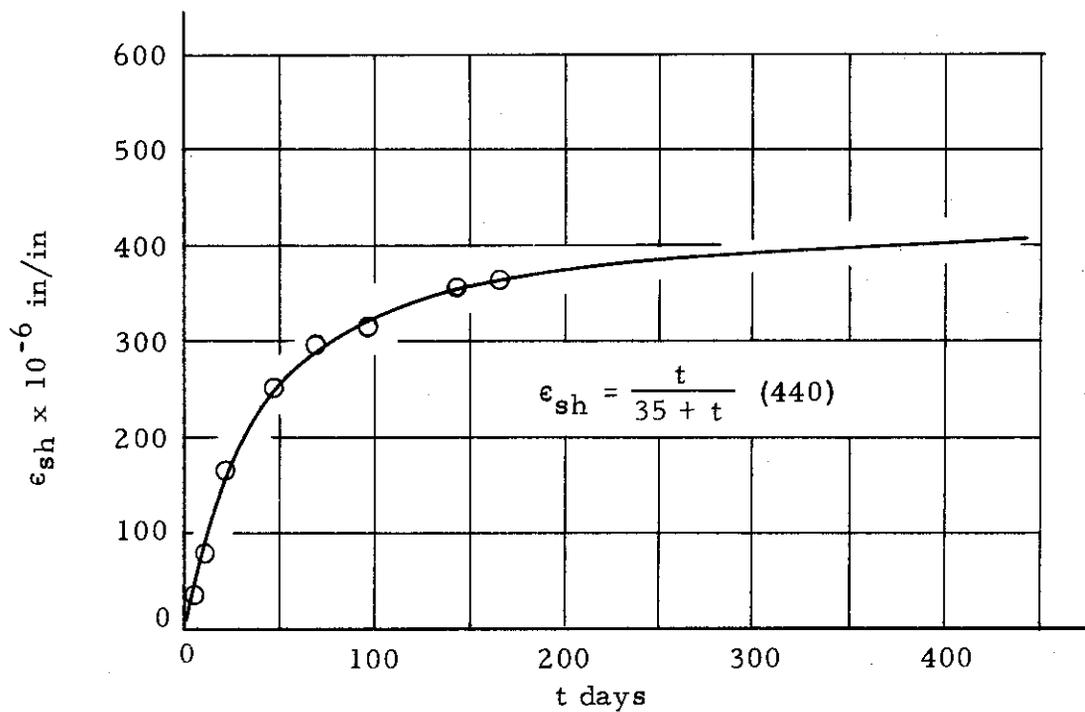

where 590 is the ultimate shrinkage strain $\times 10^{-6}$ in/in. Figures 33 and 34 show these equations compared with observed data points.

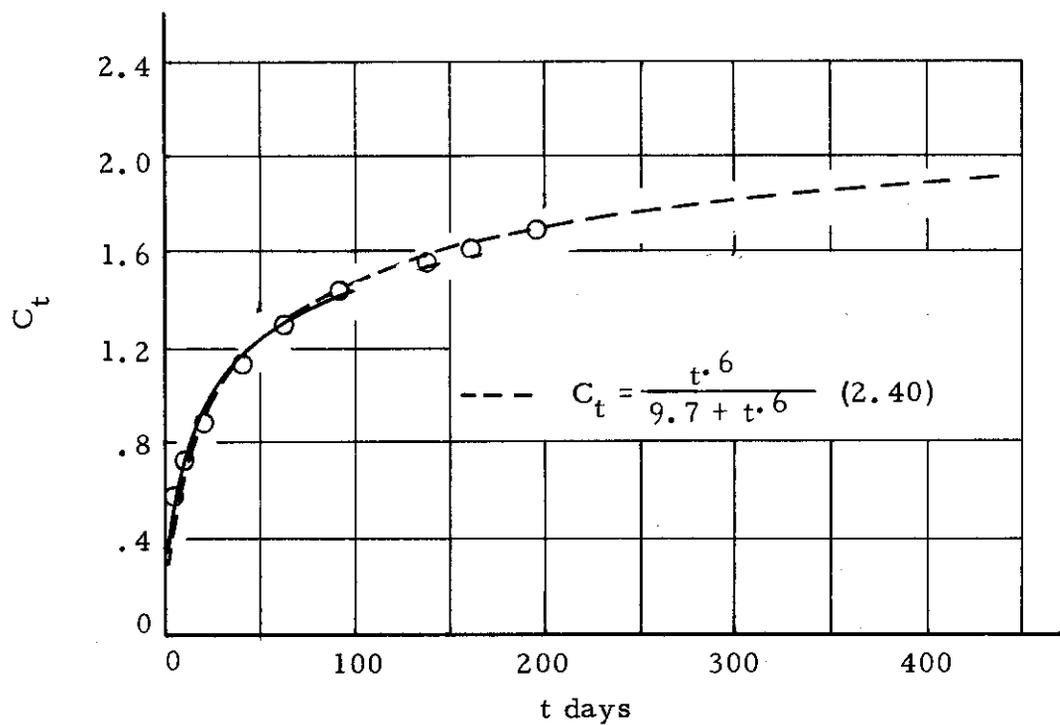

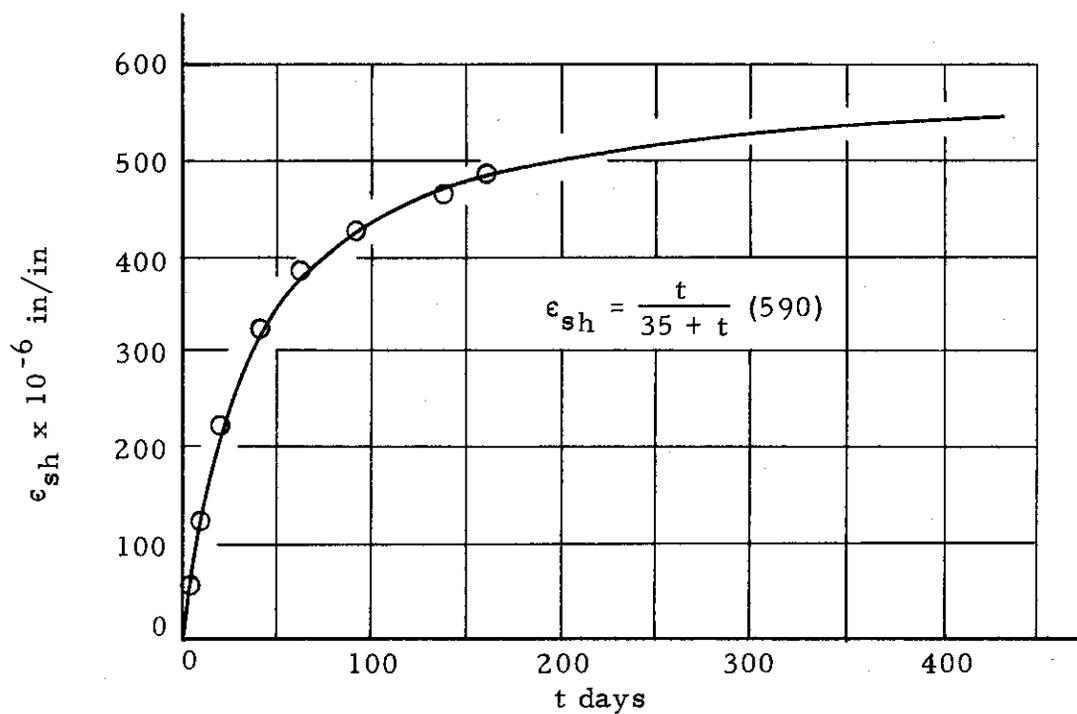

5.4 Idealite - Idealite Company

The creep coefficient and shrinkage prediction equations determined from these data are listed below:

$$C_t = \frac{t^{0.60}}{10.3 + t^{0.60}} (1.75) \quad (59)$$

where 1.75 is the ultimate creep coefficient; and

Fig. 31 C_t vs. t , Mix B-4Fig. 32 ϵ_{sh} vs. t , Mix B-4

Fig. 33 C_t vs. t , Mix CW-4Fig. 34 ϵ_{sh} vs. t , Mix CW-4

$$\epsilon_{sh} = \frac{t}{30 + t} (620) \quad (60)$$

where 620 is the ultimate shrinkage strain $\times 10^{-6}$ in/in. Figures 35 and 36 show these equations compared with observed data points.

The curves shown in Figures 35 and 36 are an average of two different mixes (I-1 and I-3) with the same mix proportions and curing conditions. Also shown in Figure 35 is the creep coefficient vs time curve for the single steam cured test which has the same mix proportions as the moist cured concrete.

Concrete steam cured 2-3 days and immediately loaded may be assumed to exhibit the same creep vs. time characteristics as concrete which has been moist cured 7 days and immediately loaded. However, in these tests the concrete was steam cured 2-3 days and loaded at 7 days age. Therefore, the creep coefficient data in Figure 35 were increased by 6% (see Fig. 7) to correct for the delay in age of loading. Similar correction factors are not available for steam cured shrinkage data; therefore, no attempt was made to formulate an expression for the steam cured shrinkage. It is recommended that reference (25) and other sources be consulted for properties of steam cured concrete because of the limited testing in this investigation.

Figures 37-40 show a comparison of observed creep vs. predicted creep for the four mixes at various stress levels. The observed initial strain, ϵ_i at each stress level was used to predict creep strain $\epsilon_c = C_t \epsilon_i$. If ϵ_i is not available it may be computed as $\epsilon_i = \sigma E_c$.

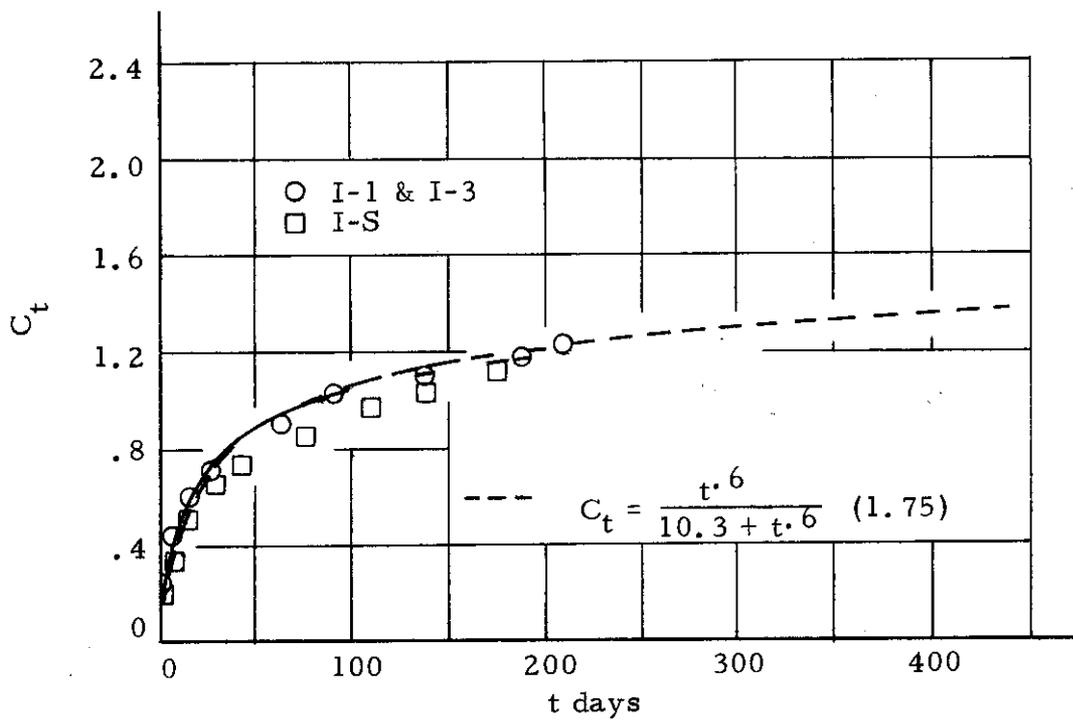

Fig. 35 C_t vs. t , Mix I-1 & I-3, I-S

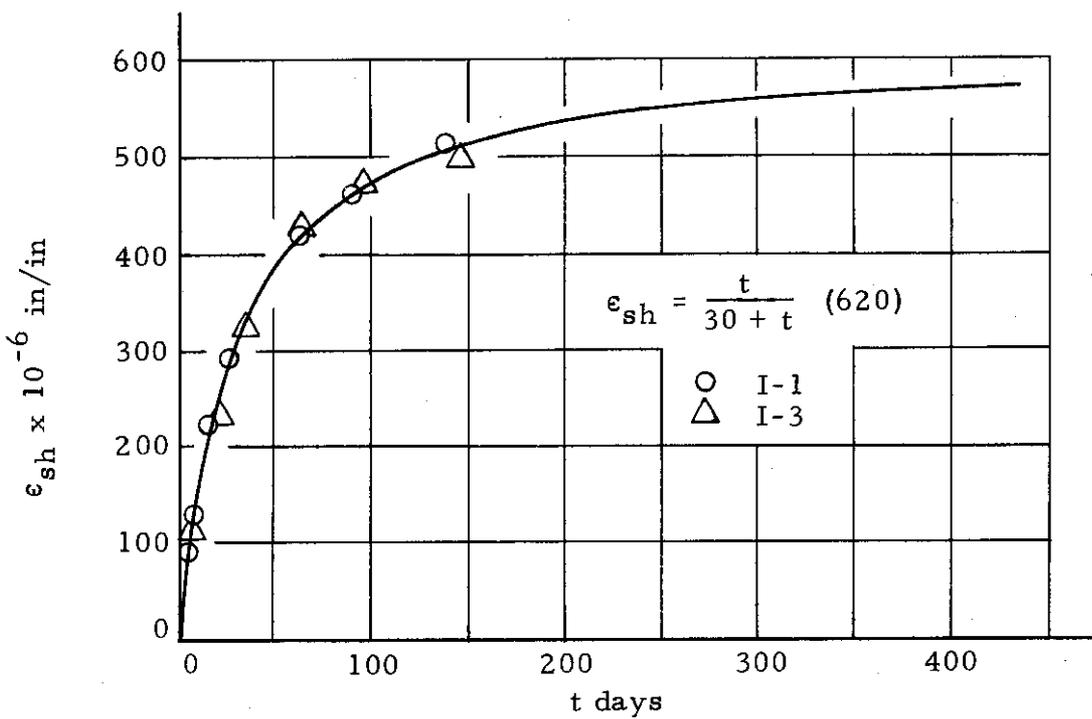

Fig. 36 ϵ_{sh} vs. t , Mix I-1, I-3

The predicted creep values in Figures 37-40 are shown to occasionally deviate 15 - 20 percent from observed behavior during the first several months of loading. For all stress levels the error of prediction is shown to decrease with time and, in general, the error does not exceed 10 percent after one year.

5.5 General Prediction Equations for Sand-Lightweight Concrete

In order to verify both the form of Eqs. (12) and (33) and the constants suggested for use in these equations for the prediction of the creep and shrinkage characteristics of sand-lightweight concrete, general equations for the materials tested in this study were evaluated by averaging the variable terms C_u and d in Eqs. (53, 55, 57, 59) and $(\epsilon_{sh})_u$ and f in Eqs. (54, 56, 58, 60).

Figures 41 and 42 show these general equations graphically and compare them to the data observed in this experimental program.

The equations are:

$$C_t = \frac{t^{0.60}}{10.5 + t^{0.60}} \quad (2.05) \quad (61)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} (570) \times 10^{-6} \quad (62)$$

These equations and all prediction equations for specific sand-lightweight aggregate concretes presented in this section have been developed for standard conditions and the correction factors suggested

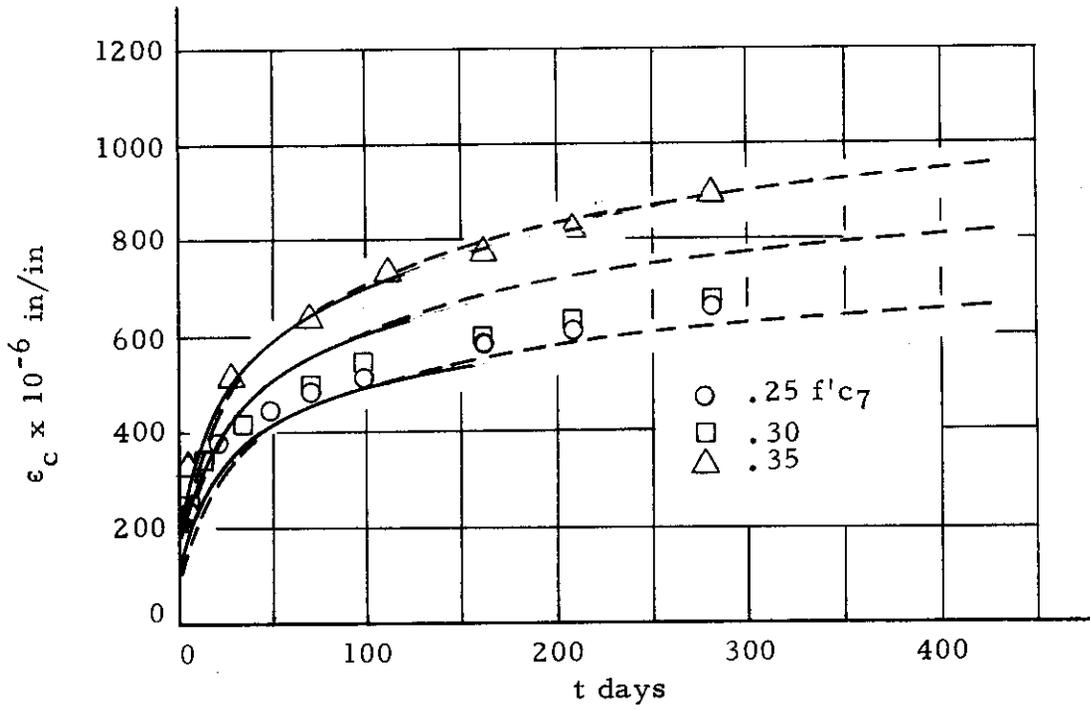

Fig. 37 Predicted vs. Actual Creep, Mix H-1

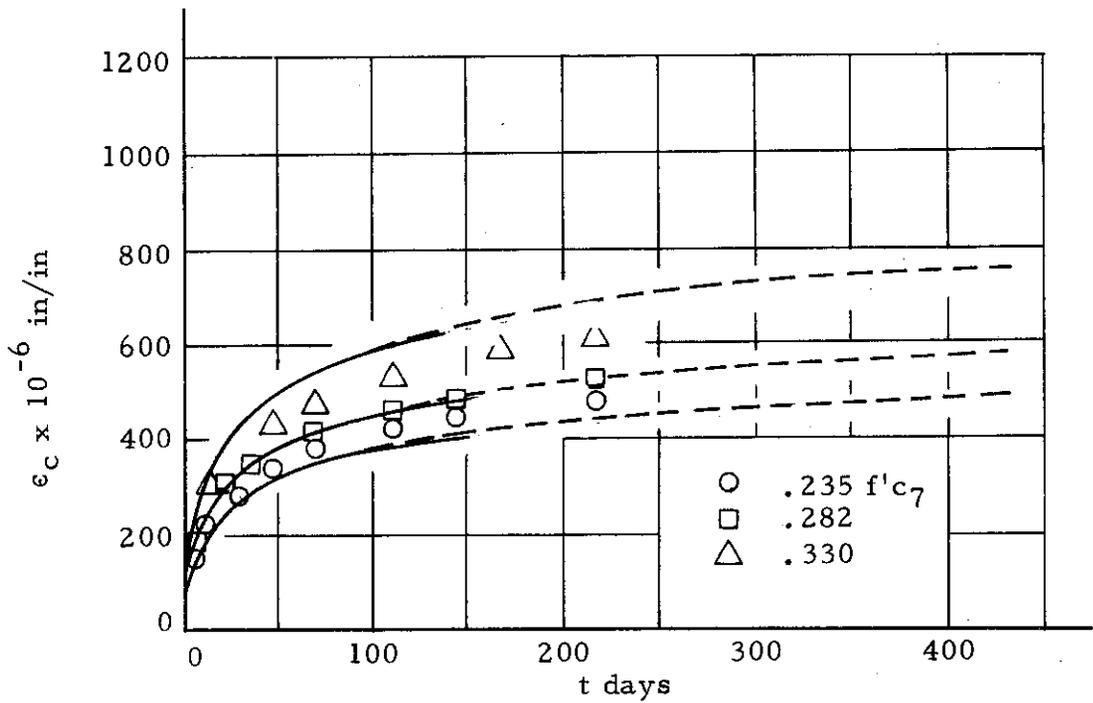

Fig. 38 Predicted vs. Actual Creep, Mix B-4

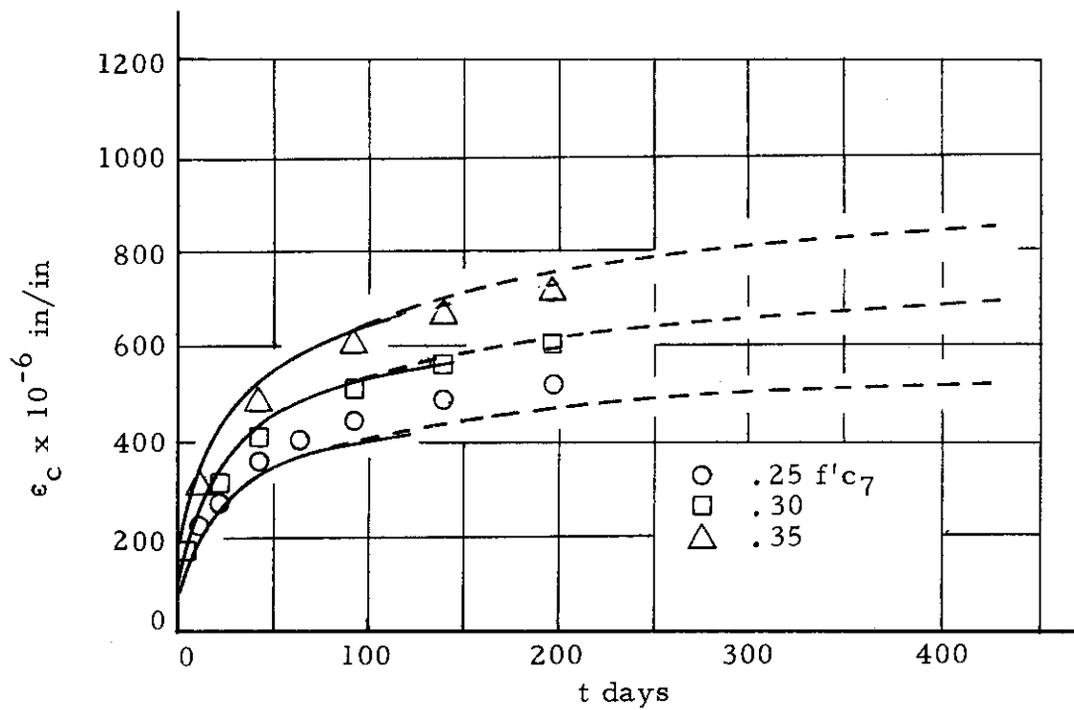

Fig. 39 Predicted vs. Actual Creep, Mix CW-4

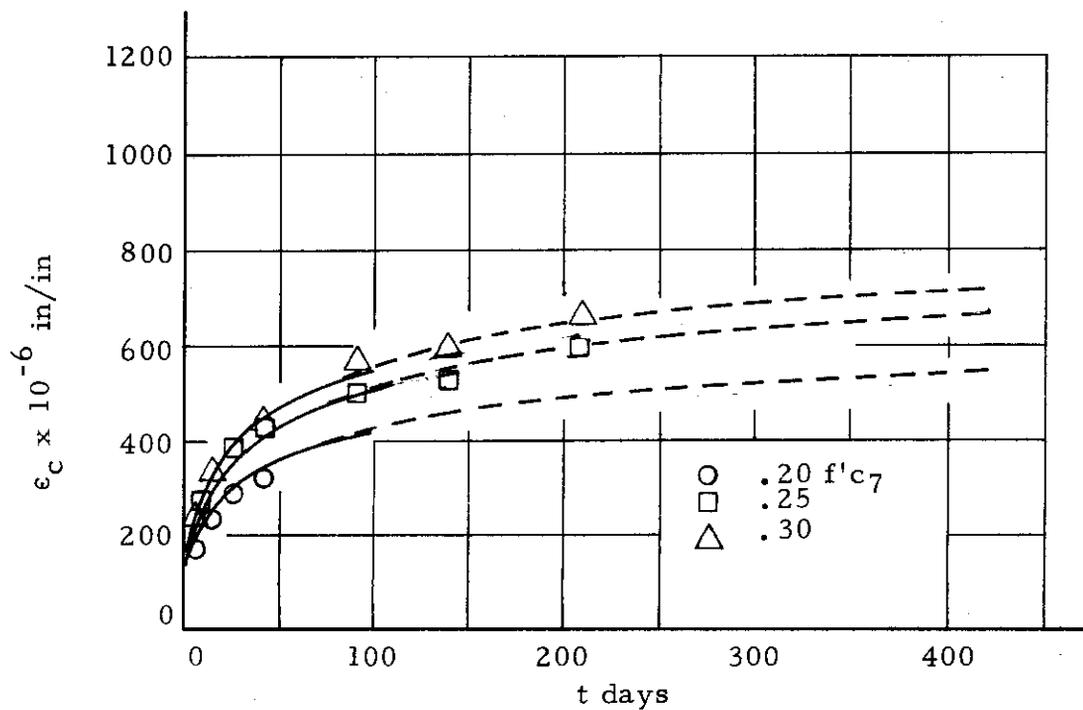

Fig. 40 Predicted vs. Actual Creep, Mix I-1

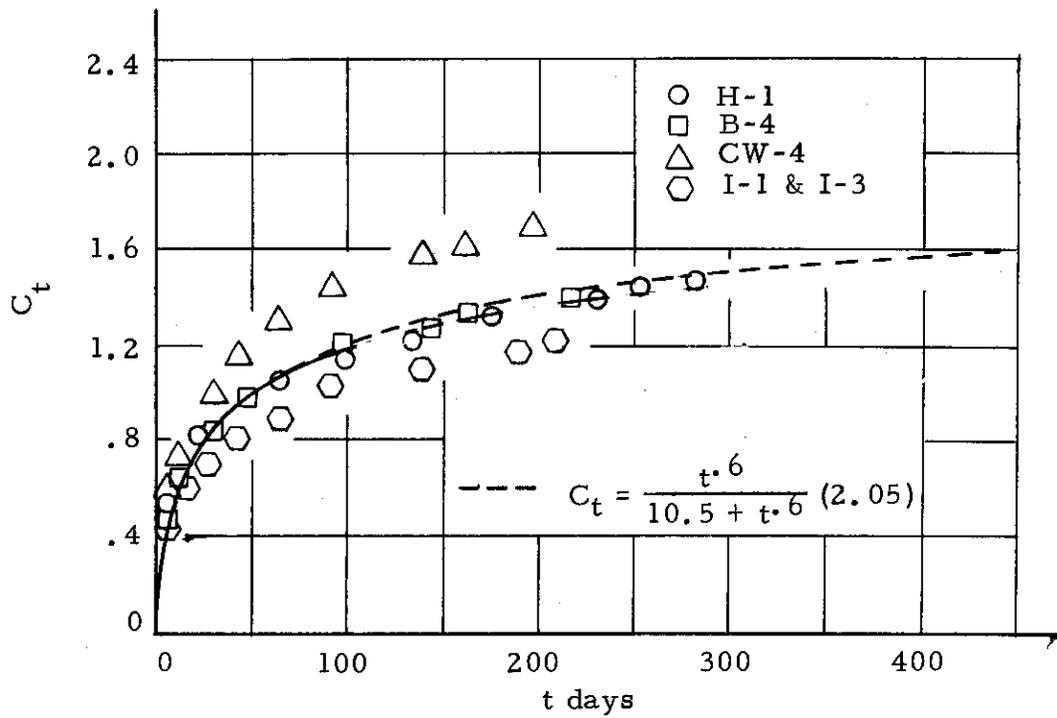

Fig. 41 General Sand-Lightweight Creep

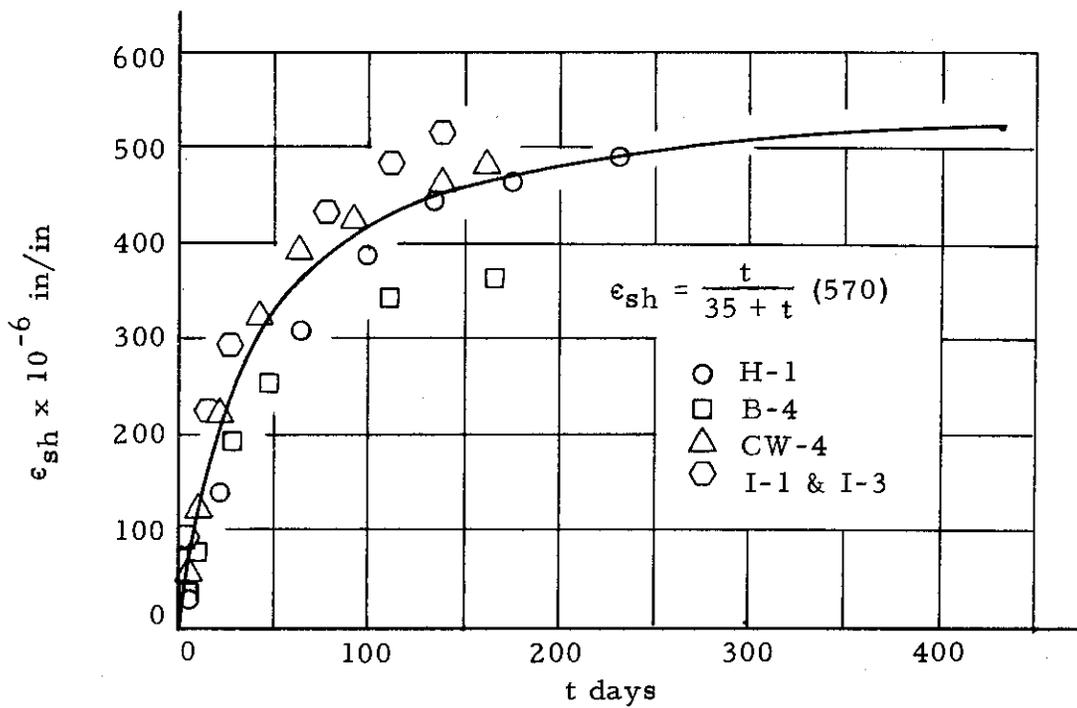

Fig. 42 General Sand-Lightweight Shrinkage

in Chapter 2 should be used to evaluate the time-dependent deformation of specimens subjected to other than standard conditions. It can be seen from the figures that the general equations represent the data with reasonable accuracy, verifying at least the general form of the equations selected.

Figures 43 and 44 show a comparison between Eqs. (61) and (62) and equations (12) and (33), which were developed in Chapter 2, and are recommended as representative of the creep and shrinkage characteristics of the material tested herein.

$$C_t = \frac{t^{0.60}}{10 + t^{0.60}} \quad (2.00) \quad (12)$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} (785) \times 10^{-6} \quad (33)$$

The general creep prediction equation developed from the analysis of the data obtained from the University of Iowa tests is almost identical to the general equation developed from the data taken from the literature (Eq. (12)). However this is not the case for the shrinkage prediction equations. The equation developed from the Iowa tests predicts shrinkage values about 25% lower than those predicted by the general equation developed in Chapter 2 (Eq. (33)). Although this is not a significant difference from a design standpoint it is felt that with additional experimentation and a slight modification in the general form of

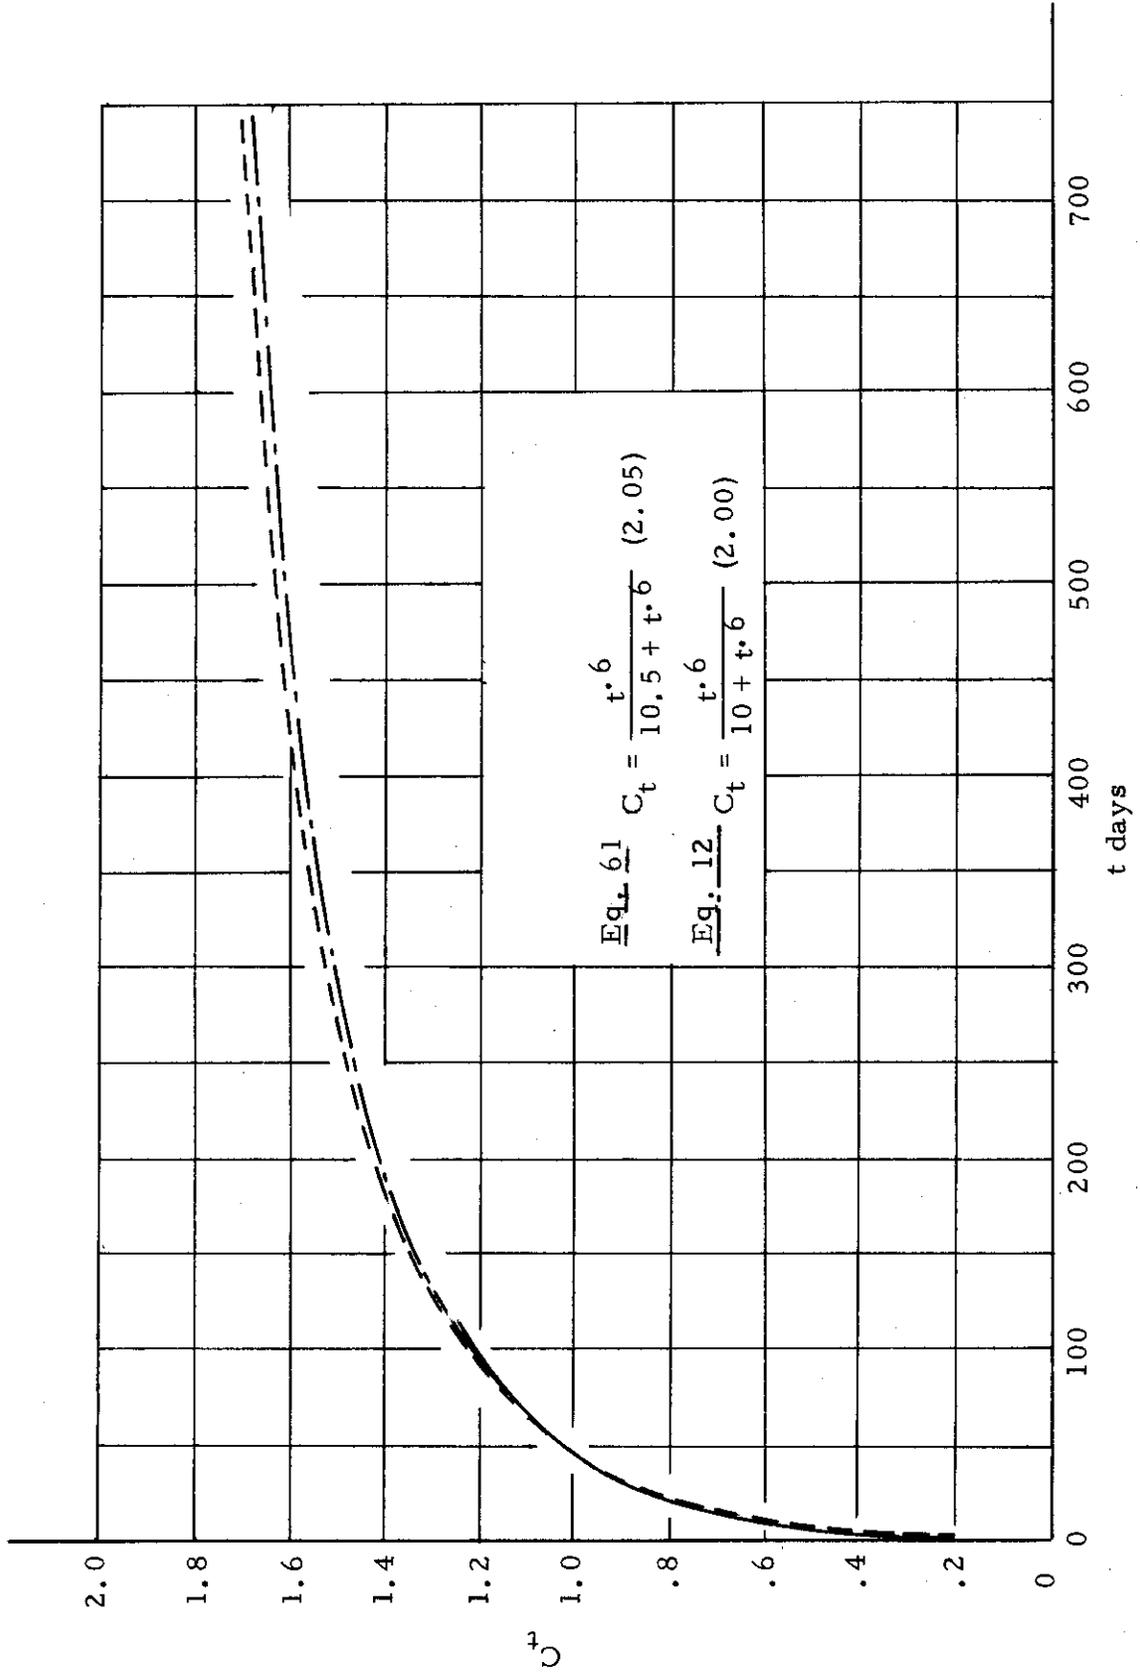

Fig. 43 Comparison of General Creep Equations for Sand-Lightweight Concrete

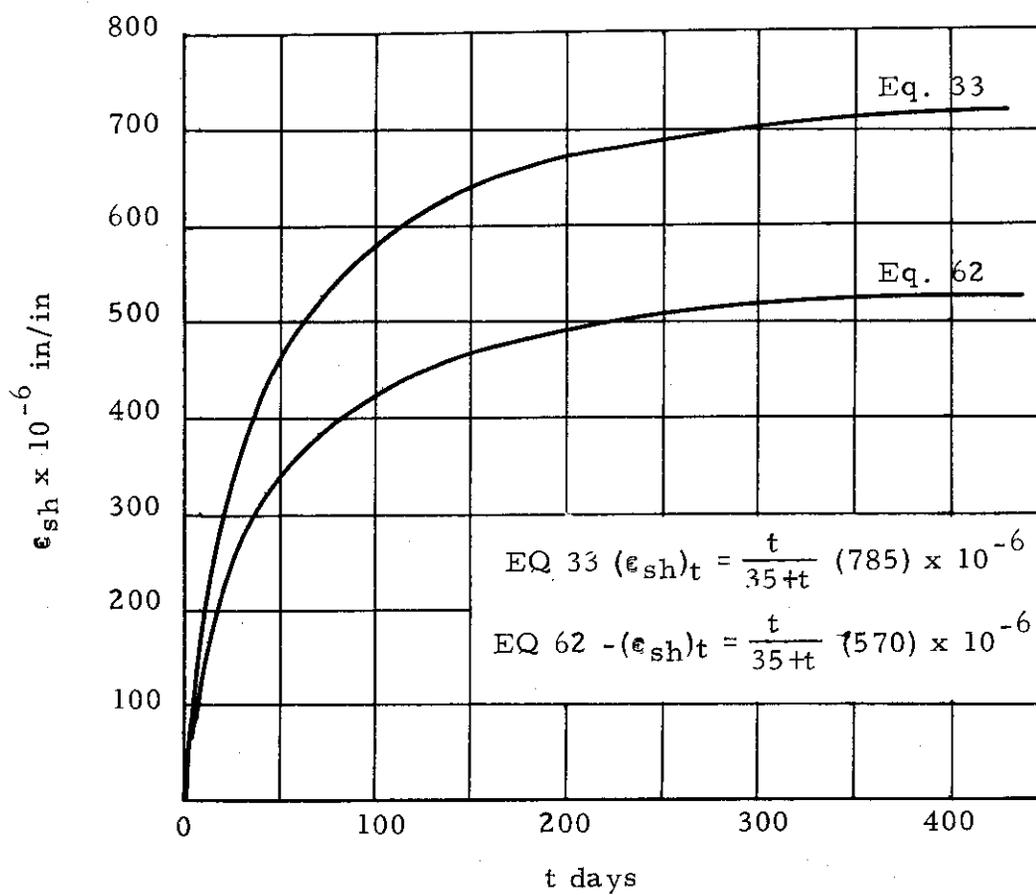

Fig. 44 Comparisons of General Shrinkage Equations for Sand-Lightweight Concrete

the shrinkage equation (i. e., a change in the value of the exponent e in Eq. (2)) would yield better results. However there was not sufficient data available to allow such modification.

CHAPTER 6

CREEP AND SHRINKAGE PREDICTION FROM 28 DAY DATA

All of the equations developed this far are suggested for use by the designer, only when experimental data is not available. For example, if any of the materials investigated in this program (see Chapter V) are to be used in a design project, it is suggested that the equations appropriate for those materials be used to predict creep and shrinkage characteristics (e. g. for moist cured Idealite sand-lightweight concrete use equations 59 and 60). When specific equations are not available it is suggested the appropriate general equations (see Chapter II) be used to predict creep and shrinkage characteristics (e. g. for moist cured normal weight concrete use equations 9 and 30).

In the following sections prediction methods based on a minimal amount of laboratory data are developed for use in those cases when the nature of the structure requires more accurate prediction, or for use in those cases when it is considered economically feasible to perform some laboratory tests.

6.1 Creep Prediction From 28 Day Data

If the general form of Eq. (1) is assumed to accurately represent the creep-time relationship, it can be seen that only one point on an experimental creep-time curve is required to solve the equation for

C_u (i. e. if d and C_t at any time are known then Eq. (1) becomes

$$C_u = C_t / \frac{t^{0.6}}{d + t^{0.6}} \quad (63)$$

and C_u can be evaluated, thereby giving a continuous equation for creep as a function of time).

The 28 day prediction method was developed using the data obtained from the experimental program described in Chapter V and therefore the constant d was taken to be 10.5 in the initial development. The method was then verified by applying it to the data obtained from the literature and discussed in Chapter II. In those calculations the constant d was taken to be 10.0. It should be noted that the method is valid for any reasonable value of d and has been shown to work for constants within the range of 6 to 12.

Figs. 45 thru 48 show creep coefficient prediction equations that were determined, for the four concrete mixes studied in this investigation, using 28 day data.

These equations were determined as follows. The ultimate creep coefficient was estimated by setting c equal to 0.6 and d equal to 10.5 and substituting the experimental value for C_t at 28 days into Eq. (1).

Table 3 shows a comparison of observed values and calculated values of C_t . The data indicates that 90% of all calculated values are within 10%, and 97% of all calculated values are within 15% of the observed values.

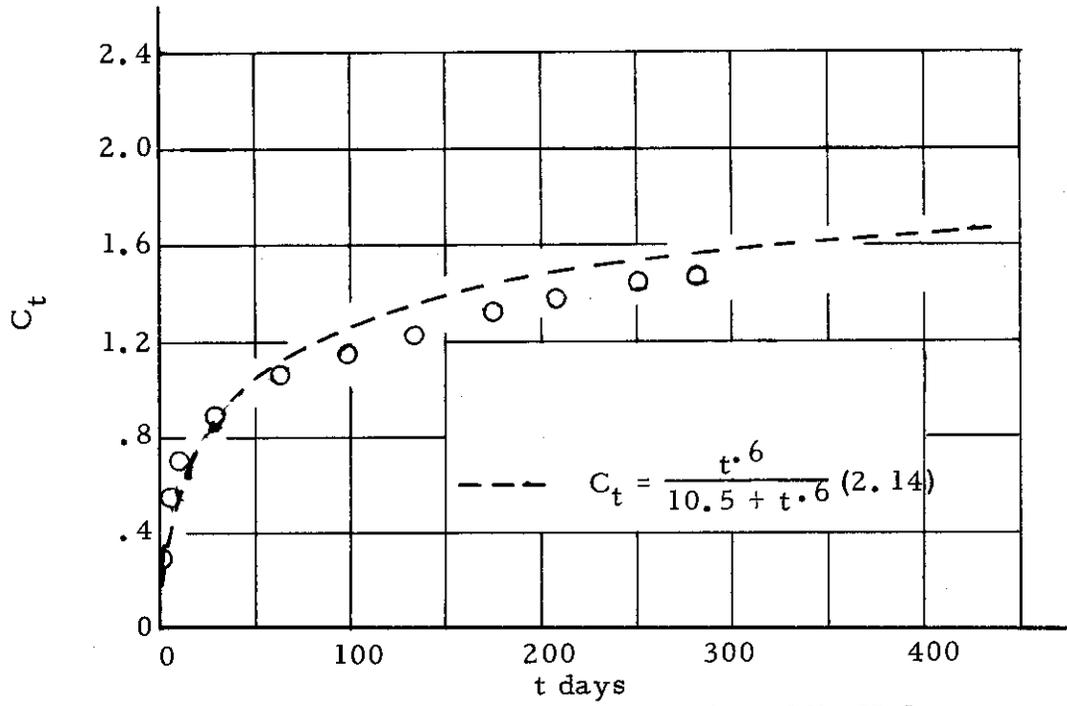

Fig. 45 28 Day Creep Prediction, Mix H-1

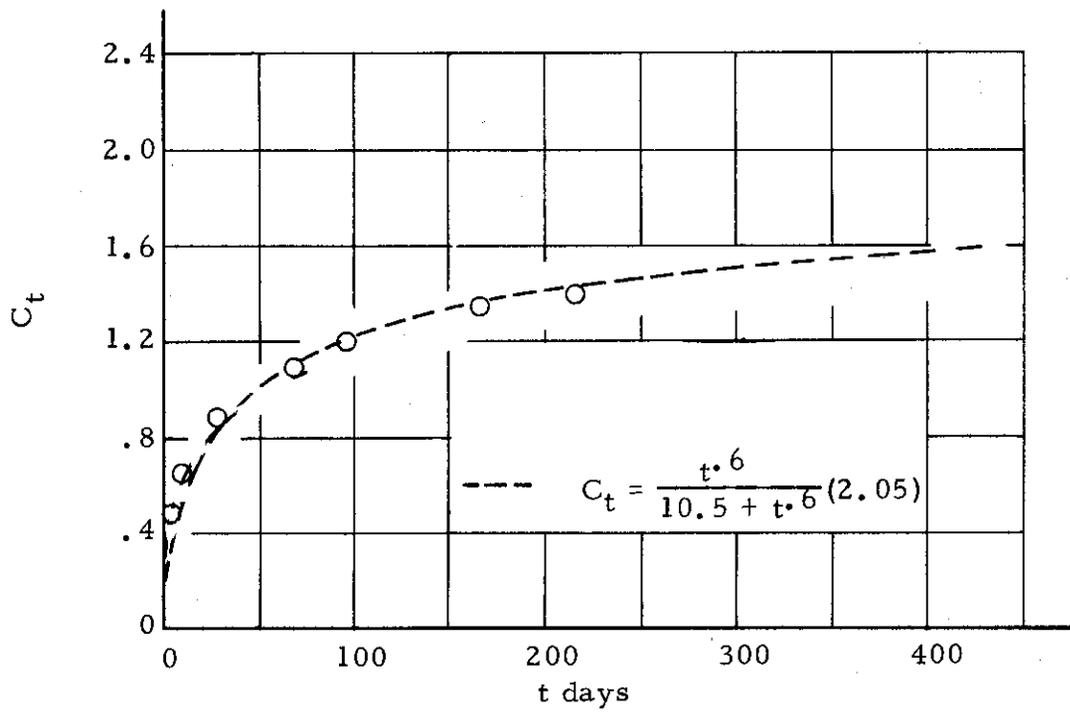

Fig. 46 28 Day Creep Prediction, Mix B-4

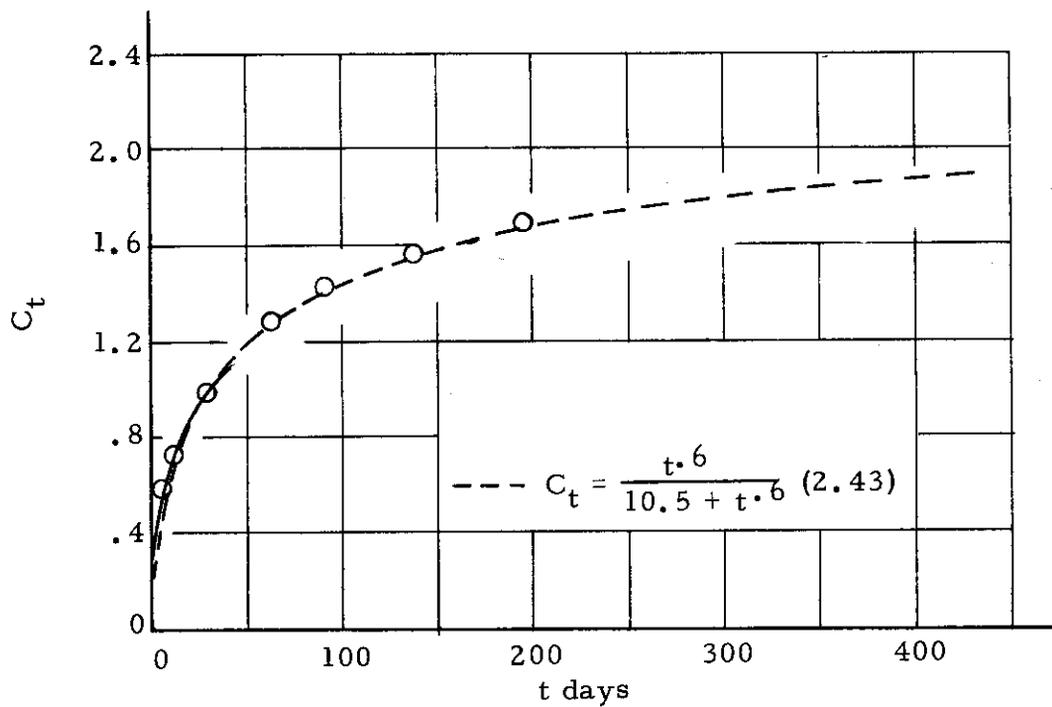

Fig. 47 28 Day Creep Prediction, Mix CW-4

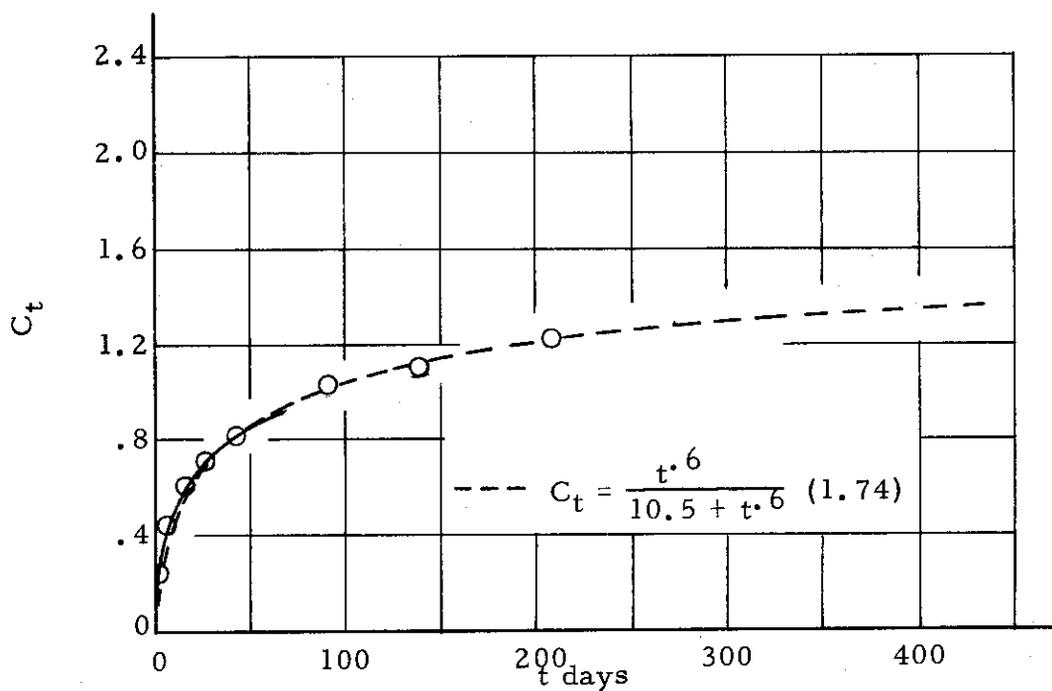

Fig. 48 28 Day Creep Prediction, Mix I-1 & I-3

The method was further verified by applying it to the data used in the development of the general equations in Chapter 2. One and two year creep coefficients were predicted from measured 28 day creep coefficients and compared to experimental values. The results of the analysis is shown in Table 4. The data shows that 53% of the calculated values are within 10%, and 83% of the calculated values are within 20% of the one year observed values. Similar figures for 2 year data are 50% of the calculated values are within 10%, and 80% of the calculated values are within 20% of the observed values. In both cases over 90% of the calculated values are within 30% of the observed values.

It can be seen that the 28 day predictions based on the experiments carried out at the University of Iowa seem to result in more accurate long term estimates. This can be attributed to the fact that the conditions of the experiments performed at the University of Iowa are known in all cases. For many of the data taken from the literature, testing conditions had to be assumed. The accuracy obtained is nevertheless excellent.

An additional measure of the accuracy of the method is indicated by the error coefficient (M). The average error coefficients for one year and two year prediction for forty sets of data taken from the literature are calculated in Table 5. It can be seen, by referring to Fig. 2 that to obtain an error coefficient of 10%, Neville and Meyers indicate that tests should be carried out for about 20 weeks. Using the

$$\frac{(C_t - C_1)^2}{n} = \frac{2.1195}{40} = 0.05299$$

$$\frac{(C_t - C_1)^2}{n} = \frac{3.0894}{40} = 0.0772$$

$$\frac{(C_t - C_1)^2}{n} = 5.299 \times 10^{-2} = 0.23$$

$$\frac{(C_t - C_1)^2}{n} = 7.72 \times 10^{-2} = 0.278$$

$$C_1/n = 84.66/40 = 2.12$$

$$C_1/n = 9.117/40 = 2.28$$

$$M = \frac{0.23 \times 100}{2.12} = \underline{10.85\%} \text{ for 365 day analysis}$$

$$M = \frac{0.278 \times 100}{2.28} = \underline{12.20\%} \text{ for 730 day analysis}$$

prediction method developed in this report, similar accuracy can be obtained with only 28 days (4 weeks) of data. A similar calculation indicates an even lower error coefficient for the 28 day predictions performed on the materials tested at the University of Iowa.

6.2 Shrinkage Prediction From 28 Day Data

The techniques described in the previous section (Creep Prediction From 28 Day Data) can also be used to obtain a continuous equation for shrinkage as a function of time, (i. e., if f and $(\epsilon_{sh})_t$ at time are known then Eq. 2 becomes

$$(\epsilon_{sh})_u = (\epsilon_{sh})_t / \frac{t}{f+t} \quad (64)$$

and $(\epsilon_{sh})_u$ can be evaluated). Figs. 49 thru 52 show comparisons between shrinkage predicted using equations based on twenty-eight day shrinkage data and measured values of shrinkage strain.

Table 6 shows a comparison between predicted and measured values of $(\epsilon_{sh})_t$. The data indicates that 72% of all calculated values are within 10%, 84% within 15% and 96% within 30% of observed shrinkage values.

The method was also applied to the data used in the development of the general equations in Chapter 2 by comparing one and two year predicted shrinkage strains with experimental values. The results of this analysis is shown in table 7. The data indicates that, for moist cured concrete, 45% of the calculated values are within 10% and 82%

(17) 8M5	370	834	660	775	675	795	1.174	1.178

$$* (\epsilon_{sh})_u = \frac{(\epsilon_{sh})_{28}}{28/35 + (\epsilon_{sh})_{28}} = \frac{(\epsilon_{sh})_{28}}{2.25}$$

of the calculated values are within 20% of the one year observed values. Similar figures for two year data are 27% of the calculated values are within 10%, and 82% of the calculated values are within 20% of observed values. In both cases all calculated values are within 30% of observed values. Since the shrinkage data was more limited than the creep data, an error coefficient calculation was not made. It is worth noting that in a recent paper Meyers et al⁽⁹⁾ suggest that for reasonable accuracy "it is desirable to conduct shrinkage tests for as long as possible, and 56 days is considered the minimum acceptable testing period." It is felt that the accuracy of the 28 day method discussed herein is acceptable.

6.3 General Remarks on 28 Day Prediction Methods

Methods to predict the long time creep and shrinkage characteristics, using 28 day data have been developed and verified. It has been shown that the expected accuracies are $\pm 15\%$ for creep prediction and $\pm 30\%$ for shrinkage prediction.

From these results it can be concluded:

1. The general form of Eq. (1) is representative of the creep-time function.
2. The general form of Eq. (2) is representative of the shrinkage function.

CHAPTER 7

RECOMMENDATIONS

In this section procedures will be recommended for

1. the prediction of creep and shrinkage properties of the four sand-lightweight aggregate concretes tested in the experimental program.
2. the prediction of creep and shrinkage properties for any type of concrete.
3. the prediction of creep and shrinkage properties of concrete using experimental data.

7.1 Creep and Shrinkage Properties of Four Sand-Lightweight Aggregate Concretes

For standard condition concrete mixes the following equations are recommended for predicting creep and shrinkage respectively:

Haydite-Hydraulic Press Brick Co.-----Eqs. 53 and 54

Haydite-Buildex, Inc.-----Eqs. 55 and 56

Haydite-Carter-Waters Corp.-----Eqs. 57 and 58

Idealite-Idealite Co.-----Eqs. 59 and 60

For conditions other than standard the values obtained from the above equations should be modified using the correction factors cited in Chapter II.

7.2 General Prediction

When specific equations such as those given in section 7.1, or experimental data are not available, it is recommended that Eqs. 9, 12,

and 15 be used to predict the creep of normal weight, sand-lightweight, and lightweight concrete respectively.

Similar equations for shrinkage prediction are Equations 30, 33, and 36 for moist cured concrete and Eqs. (42) (normal weight) and (45) (lightweight) for steam cured concrete.

The constants in the above equations have been averaged and Eqs. 6, 26, and 38 may be used to predict the creep, the shrinkage of moist cured concrete, and the shrinkage of steam cured concrete for any type of concrete.

All equations have been developed for standard conditions and should be modified for other conditions using the correction factors cited in Chapter II.

7.3 Prediction Using Experimental Data

When experimental data is available, the methods described in Chapter VI are recommended to predict the creep and shrinkage behavior of concrete. It is further recommended that the following Eqs. be used to evaluate creep and shrinkage-time functions:

$$C_t = \frac{t^{0.6}}{10 + t^{0.6}} C_u \quad (\text{moist \& steam cured})$$

$$(\epsilon_{sh})_t = \frac{t}{35 + t} (\epsilon_{sh})_u \quad (\text{moist cured})$$

$$(\epsilon_{sh})_t = \frac{t}{55 + t} (\epsilon_{sh})_u \quad (\text{steam cured})$$
